There is a growing concern about our environment and it has been realized that quick and definite measures are required if we are to preserve our planet for posterity. The rising level of greenhouse gases in the atmosphere and its consequent effect on the global climatic conditions, the depletion of stratospheric ozone, acid rain, and photochemical smog are some of the issues that have been addressed by scientists and policy makers the world over. Solutions to most environmental problems can be obtained only through collective efforts and, to ensure that such efforts are effective, it is necessary that policies and legislation are made based on scientific data on our ever-changing environment. The data must provide information on the nature of trace constituents present in the different layers of the atmosphere, their concentrations, and their chemistry. A variety of experimental techniques have been used for this purpose, such as fluorescence spectroscopy, infrared (IR) and ultraviolet/visible (UV/VIS) absorption, Raman scattering, and photoacoustic spectroscopy. All these techniques exhibit some combination of the following features: multielement detection, low detection limits (DLs), specificity for an unequivocal identification of species, accuracy, and precision. One of the experimental techniques that has found important applications in the study of the atmosphere is matrix isolation (MI) spectroscopy. In this technique, the molecules of interest are diluted in a large excess of an inert gas and sprayed onto a cold substrate held at 10 K. Under these conditions, the molecules are trapped, isolated from each other and only surrounded by inert gas atoms. Such cold, isolated molecules yield spectra that have narrow spectral widths. Furthermore, if the trapped species are reactive molecules or radicals, they are likely to have extended lifetimes in the inert cage, thus allowing their chemistry and spectroscopy to be studied at leisure. These features of MI have made it particularly useful in the study of atmospheric chemistry. The high-resolution capability enables one to use this technique as an analytical tool, as closely lying spectral features of different molecules can now be resolved – a feature that has been employed to identify and estimate trace constituents in the upper tropospheric and stratospheric samples. In conjunction with gas chromatography (GC), MI and Fourier transform infrared (FTIR), referred to as GC/MI/FTIR, offers a powerful tool with which to resolve isomeric forms of environmentally hazardous chemicals such as polycyclic aromatic hydrocarbons (PAHs), dioxins, and polychlorinated biphenyls (PCBs). Such isomeric resolution is essential, as it is well known that only certain isomeric forms are biologically active, whereas the others are not. In this respect, GC/MI/FTIR even scores over GC mass spectroscopy (MS). Analytical spectroscopy of matrix-isolated species is also done using fluorescence spectroscopy, where again the advantage of high resolution enables one to resolve isomeric forms of compounds. Where the species of interest is a free radical, electron spin resonance (ESR) is the technique of choice to study the trapped species. This is a particularly powerful tool, as free radicals are known to play an important role in a number of atmospheric processes. Another aspect of MI spectroscopy is its ability to study reaction intermediates, a feature that has been employed to study the reaction mechanisms of atmospherically important chemical and photochemical reactions. All these aspects of the technique are discussed in this article, using examples.

1 INTRODUCTION

The remarkable technological growth that the human race has seen in recent decades is not without its influence on our environment. The increase in automobile exhaust emissions, effluents and emissions from industrial processes, and harmful and toxic effects of new chemicals have all contributed to changes in our atmosphere. There has been a growing concern over this deleterious effect of human ''progress'' and it has been realized for some time now that effective measures are imperative if we are

to preserve this planet for posterity. Implementation of the Montreal Protocol in 1987 and a subsequent London Revisions in 1990 restricting the use of chlorofluorocarbon (CFC) is an example of the legislative measures that have been sought. The United Nations First Conference on Environment and Development held at Rio de Janeiro in 1992, is also testimony to the concern shown by nations world over with regard to our environment. Although legislation is undoubtedly important, the formulation of effective legislative measures requires reliable data about our environment. Information is needed on the changes in the composition of the atmosphere over a period of time, and the effect of such changes on global climatic conditions.

Our environment is continuously altered by a variety of forcing agents, both natural and man made. For example, the concentrations of greenhouse gases such as carbon dioxide, methane, CFCs, and oxides of nitrogen have been on the rise. Some of these gases are also new additions, such as the CFCs, whose role in atmospheric chemistry is a twentieth-century phenomenon. Another activity that has an impact on our environment is biomass burning, which is resorted to for clearing forests for agricultural purposes and burning postharvest residues. In developing countries, the use of wood as a fuel material also serves to contribute to this process. As a result, the atmosphere is loaded with a variety of trace gases and particles, that have a profound influence on the atmosphere, both locally and globally. For example, the emission of oxides of nitrogen and sulfur, can result in acid rain, affecting the local ecology. However, species such as CO and CH_4 have global impacts. These species can significantly lower the concentration of OH radicals, which controls the concentrations of many atmospheric trace constituents and provides a sink for some of the greenhouse gases. A reduced concentration of the OH radicals may consequently increase the concentration of these greenhouse gases. It is therefore imperative to be alert to changes which is only possible by conducting a continuous ''assay'' of the atmosphere.

Before discussing the experimental techniques used to identify the atmospheric constituents, it may be worthwhile understanding a little about the structure of the atmosphere itself. The earth's atmosphere is divided into many regions based on the temperature gradient, as shown in Figure 1.[1] The region up to a height of about 10 km above the surface of the earth is the troposphere, the height that we usually touch during air travel. The region from 10 to 50 km is the stratosphere, where a number of important photochemical reactions take place. The impact that chemical species can have on our environment depends on where they are located in the atmosphere and their reactivity towards other species present alongside. For example, ozone in the troposphere

Figure 1 Vertical temperature profiles and the different regions of the atmosphere. (Reproduced by permission of Academic Press from Wallace and Hobbs[1].)

contributes to undesirable greenhouse warming and has adverse effects on humans and vegetation, whereas its presence in the stratosphere is essential to filter ultraviolet (UV) radiation from the sun. It is therefore necessary to map the concentration profiles of the various species in the atmosphere. Such mapping is done by analyzing air samples collected over different regions on the land and sea and at different heights in the atmosphere. Furthermore, the lifetimes of these species in the atmosphere is determined by their chemical reactivity and their transport dynamics. For a clear understanding of the ever-evolving atmosphere, it is necessary to understand its composition with respect to the major and trace constituents, their chemistry, and transport phenomena.

The experimental techniques used for the study of the atmosphere can be classified into two groups. The first of these are analytical methods to identify and estimate atmospheric constituents. A number of spectroscopic techniques are used for this purpose, such as fluorescence spectroscopy, IR and UV absorption, differential optical absorption spectroscopy (DOAS), photoacoustic spectroscopy, and laser-based methods involving both photon and ion detection.[2] These techniques exhibit all

or some combination of the following features: low DLs, specificity for an unequivocal identification of species, multispecies detection, accuracy, and precision. The second category of studies are aimed at understanding the kinetics and mechanisms of reactions and reaction intermediates, which play an important role in the photochemical processes of the atmosphere. These studies are generally conducted using laser-based pump-probe methods, IR and UV absorption, and ESR spectroscopy. The first category of experiments provide information on what species are present in the atmosphere, whereas the second describes their reactivity.

This article discusses the use of MI spectroscopy for atmospheric studies, both as an analytical tool and to study reaction mechanisms and intermediates, relevant to atmospheric processes. MI is a technique in which the molecules of interest are isolated in a cold, inert gas matrix and studied using a variety of spectroscopic techniques such as IR, fluorescence, ESR, and Mössbauer spectroscopy, to name a few. The technique has been widely used to study conformations, hydrogen bonded and van der Waals molecules, and high-temperature species; its use in atmospheric studies is yet another example of its utility.

2 NEED FOR A TECHNIQUE SUCH AS MATRIX ISOLATION

To appreciate the need for the technique of MI, it is worthwhile taking a look at spectra obtained with the commonly employed gas-phase and condensed-phase sampling methods. To build up this discussion, the IR spectra of a few compounds are considered.

Figure 2 shows the IR spectra of ethylene, benzene, and benzoic acid, serving as typical examples of gas, liquid, and solid samples, respectively. Ethylene at a pressure of 1 torr was used to fill a 6 in path-length gas cell, benzene was taken as a liquid film on a zinc selenide substrate, and benzoic acid was impregnated in a KBr pellet (0.5%). All these sampling methods are popularly used in IR spectroscopy. The peaks seen in the spectra reflect absorptions corresponding to vibrations of specific groups of atoms in the molecule.

What should be noted in these spectra are the *widths* of the spectral features. The absorption peaks in Figure 2 display a width that is typically about 20–30 cm^{-1}. In the case of gas-phase samples, the spectra consist of a large number of sharp lines with the contour extending to almost 100 cm^{-1}. Very often large spectral widths or contours are undesirable, particularly in experiments where it is required to identify the constituents in a multicomponent mixture. Two closely

Figure 2 IR spectrum of (A) ethylene (gas phase), (B) benzene (liquid), and (C) benzoic acid (solid phase).

lying spectral features of two different compounds can be unambiguously resolved only if the peak width is small compared with the separation between the peaks. It is therefore necessary to be able to obtain spectra with small peak widths.

2.1 Broadening Mechanisms

To reduce the width of the spectral features, it is necessary to understand what broadens them in the first place. There are a number of reasons as to why spectral features are broadened,[3] including

- natural broadening;
- Doppler broadening;
- collisional broadening;
- distribution of molecules over a number of energy states;
- interactions between molecules.

2.1.1 Natural Broadening

This arises owing to the finite lifetimes of excited states and is a manifestation of the Heisenberg uncertainty principle. The shorter the lifetime of a state, the greater is the uncertainty in the energy of that state. Consequently, the spectral width of a transition associated with that state will be large. The experimentalist has hardly any control over this broadening mechanism.

2.1.2 Doppler Broadening

Doppler broadening is a consequence of molecular motion in a sample. The relative motion of the molecules and the source (or detector), causes the transition frequency to be shifted; the magnitude and direction of

the shift depend on the relative velocity of the molecule with respect to the source (or detector). (Recall the varying pitch of a hooting locomotive as it approaches and then recedes from you.) As the molecules in a sample have a distribution of molecular speeds given by Maxwell's distribution, the transition frequencies are also distributed over a range of values, leading to a broadened spectral profile. The higher the temperature, the greater is the width of the speed distribution and hence the larger the peak width due to Doppler broadening.

2.1.3 Collisions

The collisions that occur between molecules, both elastic and inelastic, are also responsible for broadened spectral features. Inelastic collisions tend to shorten the lifetimes of the excited states, which culminates in a broadened profile. However, elastic collisions may result in phase perturbations during absorption or emission which can result in peak broadening.

2.1.4 Energy States

The distribution of molecules over various energy states, corresponding to rotational and vibrational motion, is also a cause of broad spectral profiles. For example, the large number of sharp peaks seen in the gas-phase spectrum of Figure 2 (trace A), corresponds to transitions from a number of rotational levels of ethylene; such complexities in spectra are referred to as *spectral congestion*.

2.1.5 Intermolecular Interactions

These can also perturb energy levels, leading to spectral broadening.

Only some of the broadening mechanisms have been discussed here; there are others, such as pressure broadening, time-of-flight broadening, etc. A detailed treatment of these can be found in textbooks on spectroscopy.[3] All or some combination of these factors play a role in broadening the spectral features of a sample.

A number of these broadening mechanisms depend on the temperature of the sample. For example, if the temperature T of the sample is lowered, the width of the speed distribution decreases. As a result the Doppler width, which can be shown to be proportional to $\sqrt{T}$, also decreases. Lowering the temperature also restricts the population to only a few rotational and vibrational levels, which gives rise to spectra with fewer features. It may therefore appear that by simply lowering the temperature of the sample, one can obtain a reduction in the peak widths. However, this is not necessarily the case, as Figure 3 shows. The IR spectra of liquid trimethyl phosphate at room temperature is compared with the frozen compound at 12 K. In spite of the decrease

Figure 3 IR spectrum of trimethyl phosphate (A) liquid at room temperature and (B) solid at 12 K.

expected in the Doppler width and spectral congestion at low temperatures, almost no reduction in peak width is obtained. This is because intermolecular interactions continue to operate in the frozen sample, resulting in broad spectral features.

It is therefore necessary not only to cool the samples, but also to minimize the intermolecular interactions, by isolating the molecules from each other.

The common sampling methods mentioned earlier – gas, liquid, or solid – cannot combine low temperatures and isolated-molecule conditions. It is therefore necessary to look beyond the common sampling methods to produce *cold* and *isolated* molecules. MI spectroscopy is one such experimental technique.

Although the above discussion uses IR spectroscopy as an example, the arguments apply equally well to other branches of spectroscopy.

3 MATRIX ISOLATION SPECTROSCOPY

In an MI experiment, vapors of the sample of interest are mixed with a large excess of an inert gas, such as argon

Figure 4 Cartoon depicting the environment in (a) a matrix-isolated sample and (b) a liquid sample.

or nitrogen, and this gas mixture is then sprayed onto a cold substrate (≈10 K). The inert gas to sample ratios are typically 1000 : 1. The large excess of an inert gas ensures that when the gas mixture freezes on the substrate, the sample molecules are mostly trapped isolated from each other and only surrounded by inert gas atoms, as depicted in the cartoon (Figure 4a). To a first approximation it can be assumed that the inert gas atoms do not interact with the trapped species, which therefore reside in an inert cage. This environment is devoid of strong intermolecular interactions, as opposed to the situation for a liquid sample (Figure 4b). The low temperatures of the matrix also ensure that only the low vibrational and rotational levels are populated. Furthermore, the low temperatures and the rigid matrix cage constrain molecular motions and lead to an elimination of the Doppler width. Figure 5 shows the IR spectra of gas phase acetylene, and acetylene trapped in an argon matrix at about 12 K. The extensive rotational contour that extends over 100 cm^{-1} in the gas phase is absent in the matrix-isolated spectra, which displays a sharp peak with a width of only about 2 cm^{-1}. Cooling and isolating the molecules in an inert environment has therefore done the trick!

Apart from sharp spectral features, another important feature of the MI technique is the interaction-free environment that it provides for the trapped species. If the trapped species are reactive, such species now have extended lifetimes, simply for want of a reaction partner. Without the isolation, the reactive species would most likely annihilate themselves by reacting with each other or with the surrounding species. Spectroscopic studies of reactive species trapped in an inert matrix can therefore be made at leisure; a feature which makes it possible to

Figure 5 Comparison of IR spectra of acetylene: (A) in the gas phase, (B) trapped in an argon matrix at 12 K.

study intermediates in chemical reactions. Historically, MI was first developed for this very purpose of studying transient species, by trapping them in inert matrices.[4]

MI therefore presents a twofold advantage. First, it can be used as an analytical tool for the estimation of the constituents in an atmospheric sample. In these applications the small line widths afforded by the technique is taken advantage of. Figure 6 illustrates this aspect of MI spectroscopy, where the gas-phase and matrix isolation infrared (MI/IR) spectra of a five-component mixture consisting of ethylene and deuterated ethylene are presented.[5] It is clear that the peaks due to the different components in the mixture are clearly resolved in the MI spectra. Furthermore, the small peak widths also lead to larger peak heights, thereby rendering measurements of peak intensities more accurate. Consequently, low concentrations can be accurately measured in MI experiments. Second, the ability of the technique to trap reactive species can be used to study the structure and reactions of species involved in atmospheric chemical processes. Both aspects are highlighted in the discussions that follow.

Figure 6 IR absorption spectra of a five-component mixture of ethylene and deuterated ethylenes in the gas phase (a) and matrix isolated in nitrogen (b): a = ethylene; b = ethylene-D_1; c = ethylene-D_2 (1,1); e = ethylene-D_2 (1,2-*trans*); f = ethylene-D_4. (Reproduced with permission from Rochkind.[5] Copyright 1968 American Chemical Society.)

MI is fundamentally a sample preparation technique. Once the species are trapped in the inert matrix, a variety of spectroscopic methods may be used, such as IR, UV/VIS, and ESR spectroscopy. The studies performed on the trapped species depends on the information being sought.

3.1 Experimental Aspects

A detailed treatment of the experimental aspects of MI is given in many text books on this subject.[6–8] Only a broad outline, detailing the important aspects of the technique is presented here. The MI equipment consists of:

- a cryostat to produce the low temperatures;
- a vacuum system to house the cold tip, where the sample is deposited;
- a sample handling system and deposition lines;
- a spectrometer to record the spectra of matrix-isolated species.

3.1.1 Cryostat

A cryostat is used to produce the low temperatures required to deposit the sample and the inert gas. Cryostats are of three types.

3.1.1.1 Liquid Refrigerant-based Cryostats In these cryostats, liquid refrigerants such as helium (4.2 K), liquid nitrogen (77 K) and liquid air (90 K) are used to attain low temperatures. The earliest designs involved a tubular reservoir, in which the liquid refrigerant is filled. To this reservoir is attached a sample window on which the matrix is deposited. Where liquid helium is used, a double-Dewar arrangement is essential to minimize the evaporation loss of the expensive refrigerant. In this design, the liquid helium reservoir is surrounded by a reservoir of liquid nitrogen, the secondary refrigerant acting as a heat shield.

In later modifications, liquid helium was passed through the reservoir to which the cold finger is attached. These continuous-flow cryostats do not require a secondary

refrigerant. They are also more economical than double-Dewar cryostats, and are compact and portable.

3.1.1.2 Joule–Thomson Open Cycle Cryostat In this type of cryostat a high-pressure gas is expanded through an orifice to produce low temperatures. This design does away with the need to handle liquid refrigerants and are extremely compact. Commercial models are available that cover the temperature range 4–200 K.

3.1.1.3 Closed Cycle Cryostats This type of cryostat is the most popular. In these cryostats, which work on the principle of the Gifford–McMahon cycle, cooling is achieved by the continuous compression and expansion of He, in an enclosed space. Helium is first compressed to a pressure of about 20 bar and the heat of compression is removed by circulating cold water. The helium is then delivered to the cold head, where it expands against a piston, and eventually cools the regenerator. The expanded helium is then returned to the compressor for the next cycle. Although the initial capital costs of these cryostats are high, they involve almost no running costs and are extremely easy to handle.

3.1.2 Vacuum System

The cryotip onto which the sample is deposited is housed in a vacuum system. A vacuum system is necessary to maintain the low temperature and also to provide a clean environment in which the matrix can be deposited. A vacuum of better than 10^{-6} mbar is essential for the successful conduct of an MI experiment. The presence of impurities, apart from producing impurity peaks, can also lead to complications by forming complexes with the molecules of interest. Hence the need to maintain a high vacuum in these experiments cannot be overemphasized. A diffusion pump backed by a rotary pump is popularly used to produce the necessary high vacuum. Although diffusion pumps are easy to handle and relatively inexpensive, problems due to oil backstreaming into the vacuum chamber can at times be annoying. This problem can be surmounted by using a liquid-nitrogen trap. However, wherever possible, it may be desirable to use oil-free high-vacuum pumps, such as a turbomolecular pump.

3.1.3 Deposition of the Matrix

A variety of deposition schemes is used to prepare the matrix-isolated sample. In the simplest case, the matrix gas and the sample(s) of interest are mixed to the desired concentrations in a mixing chamber using manometric procedures and this gas mixture is then sprayed onto a cold substrate through a nozzle. The flow through this nozzle, which is generally effusive, is controlled using fine flow-control valves. Typical deposition rates are about 1 mmol h^{-1} of matrix gas. Deposition rates should be controlled to ensure good optical quality of the matrices and also to prevent any excessive heat liberation during matrix condensation. Undue temperature rise of the cold finger can cause diffusion of the solute molecules, leading to undesirable aggregation. As a variation of the above deposition procedure, the matrix and the sample can be taken in two different containers and passed through two different nozzles, referred to as a twin-nozzle system. In this set-up, mixing of the matrix gas with the sample occurs soon after effusion out of the nozzle and the mixture then deposits on to the cold tip. In such experiments, the required matrix to sample ratio is achieved by controlling the relative flow rates of the sample and the matrix gas. As a logical extension, where reactions between two precursors are to be studied, a triple-jet assembly is used, where the matrix gas and the two samples effuse out through three separate nozzles. The different nozzle designs are shown in Figure 7.

The methods of sample deposition described above are employed where stable molecules are to be studied. For the study of reactive species, variations of the above procedures are employed.[9] A stable species can be first deposited, followed by photolysis to yield the reactive species. For example, photolysis of $W(CO)_6$ in an Ar matrix yielded the reactive $W(CO)_5$ and CO. Alternatively, the reactive species can be produced in the gas phase (prior to deposition) by passing the sample(s) through an electric discharge or by subjecting it to photolysis, and the reaction products are then

Figure 7 Different nozzle designs: (a) triple-jet nozzle; (b) twin-jet nozzle; (c) single-jet nozzle; (d) photograph of a triple-jet nozzle.

trapped in the inert matrix. For example, $XeCl_2$ can be prepared by passing Xe and Cl_2 through a discharge tube.[9] As mentioned earlier, these reactive species, which normally would have instantaneously indulged in a chemical reaction destroying themselves, now have extended lifetimes in the inert cage. This technique has been exploited for studies on atmospheric chemistry, as reactive molecules expected to participate in atmospheric processes can be trapped in the matrix for spectroscopic analysis and study of their reactions.

3.1.3.1 Annealing Once the sample and matrix are deposited, a spectrum of the matrix-isolated sample is recorded. Very often, a spectrum of the sample is also recorded after annealing the matrix. Annealing is a process where the temperature of the matrix is raised to about $0.4\,T_m$, where T_m is the melting point of the matrix material. The matrix is held at this temperature for some time, (typically about 15 min to 1 h) and then recooled to 12 K. Annealing of the matrix is done for two reasons. First, it removes unstable sites in the matrix in which the sample molecules may be trapped. The sites referred to are the different environments in which the sample molecules are trapped in the lattice formed by the inert gas during deposition. One such environment is formed by substituting the sample molecules for one or more of the matrix atoms; such a site is referred to as a substitutional site and is the most likely one for large molecules. Alternatively, the sample molecules may occupy either a dislocation or an interstitial site. The interstitial site is usually too small to accommodate most molecules other than small diatomics. Dislocation sites are large but nonuniform. Although some of these sites may be unstable, they may nevertheless be formed during matrix deposition owing to the rapid freezing. The presence of these different sites may be signaled by the appearance of multiplets in a spectra. Annealing the matrix generally simplifies such spectra, by removing sites that are unstable. Figure 8 shows the spectra of trimethyl phosphate recorded after deposition and after annealing the matrix. It can be seen that with the loss of the unstable sites, the spectral features sharpen on annealing. As discussed below, the role of sites in MI spectra is particularly relevant in the study of fluorescence of species trapped in hydrocarbon matrices. Another reason to anneal the matrix is to deliberately cause diffusion of the solute molecules in an effort to drive a reaction. The diffusion may cause two molecules, (which were initially isolated) to approach each other and form aggregates. Appearance of new peaks following annealing is generally a signature of the occurrence of such reactions.

3.1.3.2 Matrix Substances must possess certain properties for them to serve as matrices. They must be *inert* so that they do not perturb or react with the trapped species. At the temperatures of the MI experiments, the substance must form a *rigid* matrix, so that the molecules of interest may be held isolated. If this criterion is not met, the trapped species will diffuse, leading to undesirable reactions. At the same time, the substance must be *volatile* at room temperature, so that it may be conveniently deposited onto the cold substrate. It is also important that the matrix substance must be available with a high degree of *purity* and not have any spectral absorptions in the region of interest.

Figure 8 MI/IR spectrum of trimethyl phosphate in nitrogen (A) as deposited and (B) after annealing at 35 K for 15 min.

Inert gases and nitrogen generally meet the above criteria and are used as matrix gases. Among the inert gases, argon and to a lesser extent neon and xenon are commonly used. These gases are popular where IR spectroscopy is used to probe the trapped species, as these matrix materials do not have any IR absorptions. There have been specific instances where other materials, such as carbon dioxide, water (or D_2O), and hydrocarbons, have been used as matrices. These are discussed later.

Figure 9 Photograph showing the MI set-up: (A) is the FTIR spectrometer, (B) the closed cycle helium cryostat, and (C) the mixing chamber.

3.1.4 Spectrometer

Once the sample molecules are isolated in the matrix, they are studied by using any of the spectroscopic methods, such as IR, fluorescence, or ESR spectroscopy. The choice of the spectroscopic technique is generally determined by the type of information one is looking for. For example, an analytical exercise is usually undertaken using IR and fluorescence spectroscopy, whereas studies on free radicals (which may be reactive intermediates in a photochemical reaction), are usually performed using ESR and IR spectroscopy.

A MI set-up is shown in Figure 9. Details of the experimental and theoretical aspects of the technique can be found in a number of treatments on this subject.[6–10]

4 APPLICATIONS

4.1 Analytical Spectroscopy

MI has been used as an analytical tool for the detection and quantitative estimations of trace constituents in the atmosphere. As mentioned earlier, this application stems from the fact that the spectral features in MI experiments have small line widths, which makes it possible to resolve closely lying peaks of the different constituents.

Analysis of air samples can be classified into two groups: first, those that monitor the occurrence and concentrations of species that have a long-term effect on the climatic conditions of the earth; second, those that serve to identify the presence of hazardous chemicals that pose a threat to the local environment. Examples of the first class are the study of air samples from the upper troposphere and stratosphere for species such as OH radicals, oxides of nitrogen, sulfur, and halogens, carbonyl halides, halomethanes, and peroxides. It is now realized that these species play an important role in the earth's atmospheric chemistry,[11] and data on such species serve as inputs for atmospheric modeling exercises. Examples of the second class are the study of air samples to monitor the presence of toxic substances such as PAHs and PCBs. In these analyses the air samples are collected from nearer to the earth's surface.

The use of MI spectroscopy for these analytical studies in conjunction with IR, fluorescence, and ESR spectroscopy is now reviewed.

4.1.1 Matrix Isolation Infrared Spectroscopy

First, the use of this technique for studies on upper tropospheric and stratospheric samples is considered, together with problems associated with such studies. Studies on near-ground-level samples are then discussed.

4.1.1.1 Samples from the Upper Troposphere and Stratosphere A number of species that dominate the chemistry in these regions of the atmosphere are labile; it can therefore be extremely difficult to retain the identity of these species till they are brought back to the laboratory for MI studies. Sample collection techniques that retained the identity of the species had therefore to be worked out. In one of the first attempts, a closed cycle refrigerator was transported in a military aircraft to collect air samples at altitudes of around 15 km. The cryostat was then brought back to the laboratory for analysis. Although these first attempts by Snelson,[12,13] did not particularly succeed in obtaining MI data, they nevertheless paved the way for future studies.

The work of Griffith has contributed significantly towards the development of reliable sample collection methods and pretreatment.[14] Associated with the problem of sample collection, the choice of a suitable matrix material is also an important question to be addressed, which is discussed first.

Choice of the Matrix Material. It was recognized that instead of the commonly employed matrix gases, such as Ar or N_2, there was a significant advantage to be derived by using the CO_2 present in the air sample itself as the matrix gas.[14] Carbon dioxide is present in air to the extent of 350 ppmv. Other trace gases are present in the air sample, at concentrations about 1000 times lower. For example, N_2O is present at levels around 300 ppbv. If the CO_2 present in the air is used as the matrix, the sample to matrix ratio, (such as N_2O/CO_2) would be about 1 : 1000, which is typical in MI experiments. If argon had been used as the matrix, as is usually done in MI experiments and the air to argon ratio were 1 : 1000, then the CO_2 to argon ratio would be about $1 : 3 \times 10^6$, and the N_2O to argon ratio would be about $1 : 3 \times 10^9$. These concentrations are extremely low. The choice of CO_2 as the matrix, can therefore be seen to preconcentrate the trace constituents, and is the key to the success of the experiment. The use of CO_2 as the matrix poses problems of interfering IR absorption bands, as CO_2 has strong IR absorptions. However, useful spectral windows are still available with this matrix for use in trace gas analysis. Interestingly, these interfering CO_2 bands have been used to advantage to monitor the thickness of a CO_2 matrix, as discussed later.

Method of Air Sample Collection and Pretreatment. Having decided on the matrix, the next question to be addressed is the method to be adopted to collect the atmospheric samples. It is necessary to be able to collect the air sample and transfer it to the cold finger along with the matrix gas, CO_2, with little loss of sample integrity. Obviously, the best method would be to deposit the air sample directly on to a cold substrate without any sample treatment. If the substrate temperature is maintained at 77 K, only CO_2 (to be used as the matrix) and other nonvolatile constituents would deposit. This procedure was not often successful, particularly for IR studies, because the water normally present in the air samples to the extent of about 1 ppmv led to poor-quality matrices. Furthermore, the condensation of CO_2 in the presence of large quantities of N_2 and O_2, the major constituents of air, also resulted in poor-quality matrices. Hence some amount of sample preparation was necessary before the air sample could be analyzed. After considerable research effort, a two-step process was devised, to prepare dry air samples.[14] The field samples were drawn into a cryosampler, and maintained at liquid nitrogen temperatures. In the laboratory, the sample was evaporated by raising the temperature of the cryosampler carefully to a predetermined value. This temperature of evaporation was determined by the amount of water expected to be present in the field sample. Where the water content was low, such as in upper tropospheric samples, the temperature of evaporation was maintained at about $-50\,^{\circ}C$. However, where the water content was expected to be high, such as in air samples collected nearer to the earth's surface, lower evaporation temperatures were employed or drying agents such as P_2O_5 were used. Care must be exercised during such drying procedures as chemical modifications of the sample species may occur, which is obviously undesirable.

Quantification Procedure. Once the matrix-isolated sample is prepared, quantification of the trace species is done using the celebrated Beer–Lambert law, although the application of the law in this case needs a little elaboration. The Beer–Lambert law can be written in the form (Equation 1)

$$A = \varepsilon \times c \times d \tag{1}$$

where A is the integrated absorbance of the analyte, ε is the integrated absorption coefficient expressed in appropriate units, c is the concentration of the analyte in the sample (which in this case is the concentration of the analyte in the CO_2 matrix), and d is the matrix thickness. In the usual application of the Beer–Lambert law, d represents the path length of the cell containing the sample. This quantity is generally known a priori, or at least remains a constant and can therefore be absorbed into a calibration plot. In the MI experiments, the matrix thickness d is a variable, depending on the rate and duration of deposition, and must therefore be measured for each experiment. The matrix thickness is usually measured using interference techniques with an He–Ne laser. Griffith and group devised a method that used the intensity of CO_2 (matrix) absorption line as a thickness monitor. A series of measurements was made of the

intensities of the different CO_2 absorption lines, together with a direct thickness measurement using the He–Ne interference method. This data enabled the absorption coefficient of the different lines in the CO_2 IR spectrum to be evaluated. Using this data, the thickness d of the CO_2 matrix can be calculated, simply by monitoring the integrated absorbance of any of the CO_2 peaks. A detailed discussion of this method is given by Griffith.[14]

For the estimation of the trace gas concentrations, calibration plots are obtained by taking known concentrations of the trace gas in question, in a CO_2 matrix and measuring the intensities of its absorption line. From the calibration plot, one evaluates the concentration of the trace gas with respect to CO_2 in the atmospheric sample. If the mixing ratio of CO_2 in air is known, the concentration of the trace gas in air can be estimated. The mixing ratio of CO_2 in air can be separately determined by taking the air sample in a gas cell for gas-phase spectral analysis. It must be remembered that the straightforward gas-phase method cannot be applied to trace gas estimation, because the low concentration precludes such a simplistic determination.

Figure 10 provides an example of the analysis of an air sample collected from the upper troposphere from a Lear Jet.[15] Species such as $COCl_2$, OCS, and freons were identified in this sample, in addition to other carbonyl halides such as COFCl and COF_2. These species were found to be present at mixing ratios of approximately 20 pptv in the upper troposphere and increased with height in the lower stratosphere. The identification of the carbonyl halides in the upper tropospheric samples raised the question as to where they were formed. It is now believed that the carbonyl halides are formed by the oxidation of chlorinated hydrocarbons in the troposphere, and then transported to the stratosphere. (A later section describes how the oxidation of halocarbons was studied using MI spectroscopy.) Once in the stratosphere, carbonyl halides dissociate photolytically to yield free chlorine, which plays an active role in ozone depletion. The point that this study drives home is that an oxidative species from the troposphere may have an impact on stratospheric ozone depletion – a useful input for ozone-depletion models. The same study[15] also pointed out that phosgene mixing ratios of 17 pptv in the upper troposphere and 22 pptv in the lower stratosphere were greater than those estimated by models which assumed CCl_4 as the only source. These experiments therefore implied that other sources of phosgene must be present, such as $CHCl_3$, CH_3CCl_3, C_2HCl_3, and C_2Cl_4. This study is a classic example of how detection and quantification of trace species in the atmosphere can serve as useful inputs for atmospheric models.

Figure 10 MI/IR spectrum of an air sample collected in the upper troposphere from a Lear Jet. A reference spectrum of $COCl_2$ is also shown for comparison. (D.W.T. Griffith, 'Matrix Isolation Spectroscopy in Atmospheric Chemistry', in *Air Monitoring by Spectroscopic Techniques*, ed. M.W. Sigrist, Copyright © 1994 John Wiley & Sons. Reprinted by permission of John Wiley & Sons, Inc.)

4.1.1.2 Samples from Near to the Earth's Surface In the second class of analysis of air samples, the problem is to identify and measure the concentrations of hazardous chemicals, such as PAHs, chlorinated dioxin and dibenzofuran derivatives, and PCBs, that pose a threat to the local environment. In these applications involving usually stable species, GC is used in conjunction with MI spectroscopy. The sample mixture is first subjected to a gas chromatographic separation and the material that is eluted is deposited on a rotating gold-plated cryogenic surface. The samples eluting at different times are deposited on different points on the cryogenic surface. In these experiments, helium–argon mixtures are used as the carrier gas for chromatography. The argon present in this mixture serves as the matrix gas to prepare the matrix-isolated sample. The deposited chromatogram is stored on the cryogenic surface and an IR spectrum then recorded. The technique is referred to as GC/MI/FTIR, where the matrix isolation/Fourier transform infrared (MI/FTIR) detection scheme replaces the light pipe probe used in conventional GC/FTIR. The GC/MI/FTIR method is more sensitive and has a higher spectral resolution than conventional GC/FTIR. Figure 11 compares a spectrum of *N*-nitrosodimethyl amine recorded using GC/MI/FTIR with that recorded using a light-pipe-based absorption.[16] The MI/FTIR detection clearly offers spectra with better signal-to-noise ratio (S/N) than the light-pipe detection. The superior S/N in the MI/FTIR spectra is due to the signal-averaging capabilities offered by this technique. Furthermore, light pipes are usually heated to prevent

Figure 11 FTIR spectra of *N*-nitrosodimethylamine obtained by MI/GC/FTIR (a) and conventional light-pipe GC/FTIR (b). (Reproduced from the *Journal of Chromatographic Science* by permission of Preston Publications, a Division of Preston Industries, Inc. from Schneider et al.[16])

condensation of the eluted samples. The heating gives rise to an IR background in the light-pipe detection.

The single most attractive feature of GC/MI/FTIR is its ability to distinguish between isomers.[17,18] This advantage is of paramount importance, as it has been shown that biological toxicity is often highly isomer specific. For example, amongst the polychlorodibenzo-*p*-dioxins, the 2,3,7,8-tetrachloro isomer is the most toxic.[17] Similarly, benzo[*a*]pyrene (B[*a*]P) is a potent carcinogen, whereas its isomer benzo[*e*]pyrene is significantly less hazardous. From the point of view of environmental monitoring and waste management, it is therefore essential that the analytical technique possess the ability to resolve isomers. Figure 12 (trace A) shows the GC/MI/FTIR spectrum of a fraction that eluted out of the GC column at a certain time (31.58 min).[17] This spectrum did not find a match in the MI/IR spectral library, and it was suspected that the eluted fraction may contain a mixture of an isomer pair. It is clear from traces B and C, which

Figure 12 MI/IR spectrum (trace A) of component of a filter extract with a retention time of 31.58 min, (B) chrysene reference spectrum, (C) triphenylene reference spectrum. (Reproduced by permission of Society for Applied Spectroscopy from J.W. Childers, N.K. Wilson, R.K. Barbour.[17])

are reference spectra of chrysene and triphenylene, that the eluted fraction contained both these isomers. The example clearly demonstrates that compounds eluting simultaneously can still be differentiated using MI/FTIR. In this regard, GC/MI/FTIR even scores over mass spectroscopic detection, which enjoys superior DLs, but is not always capable of resolving isomeric species. For example, electron impact ionization mass spectra of chrysene and triphenylene yielded identical parent ions, similar fragmentation patterns and only subtle differences between the two spectra, making differentiation between the two isomers difficult. Similar resolving capabilities were also demonstrated for the B[*a*]P/benzo[*e*]pyrene pair, and benzofluoranthene isomers.[17]

4.1.2 Matrix Isolation Fluorescence Spectroscopy

Fluorescence spectroscopy has been extensively used as an analytical tool for condensed- and gas-phase samples. Compared with absorption spectroscopy, fluorescence spectroscopy has superior DLs, which has made it the technique of choice for trace level estimations.

Obtaining sharp absorption and emission lines is again a principal motivation for doing fluorescence spectroscopy of matrix-isolated samples. However, unlike in IR spectroscopy, where inert gases and nitrogen are excellent matrices, the choice of the matrix is not so straightforward in fluorescence. The same considerations as those discussed earlier for sharpening of spectral lines apply here too, except that the site effects are extremely important

in this case. Molecules trapped in different environments can display a multitude of spectral features. If a matrix can be chosen in which the molecules can be trapped in a few well-defined sites, spectral simplification may occur, leading to sharp spectral features, referred to as the Shpol'skii effect.[19] Hydrocarbons, such as hexane and octane, have often proved to be successful Shpol'skii matrices. It has been realized that the best matrices are those in which one of the dimensions of the solute molecules is similar to the length of the hydrocarbon chain. In such systems, the solute preferentially occupies a well-defined site, leading to line narrowing. Figure 13 shows the laser-induced fluorescence spectra of the environmentally important B[*a*]P trapped in heptane and octane matrices.[20] It can be seen that the spectrum in the octane matrix is sharper than that in the heptane matrix, which displays a multiplet structure. The sharp spectral feature in the octane matrix may be useful in characterizing the trapped species for analytical applications.

Furthermore, the trapped species exhibit sharp features in absorption too, which allows one to selectively excite a particular species in a well-defined site, using a narrow-band excitation source, such as a dye laser. This aspect was convincingly presented by D'Silva and Fassel.[21] They showed that each component in a multicomponent mixture can be selectively excited to obtain a fluorescence spectrum corresponding to each of the trapped species. Figure 14 shows the spectra of four different PAHs, obtained by a selective excitation of each of the species in the mixture, using dye laser excitation. The sample was a solvent-refined coal liquid sample trapped in an *n*-octane matrix. Occasionally, a partial overlap of the absorption lines may lead to spectra of more than one compound

Figure 13 Laser-induced fluorescence spectra of B[*a*]P in a solid solvent-refined coal sample in (a) heptane and (b) octane matrices at 15 K. (Reproduced with permission from M.B. Perry, E.L. Wehry, G. Mamantov,[20] Copyright 1989 American Chemical Society.)

Figure 14 Site-selective laser-excited fluorescence spectra of pyrene, 4-methylpyrene (4-MP), B[*a*]P, and benzo[*k*]fluoranthene (B[*k*]F) in a solvent-refined coal sample. (Reproduced with permission from A.P. D'Silva, V.A. Fassel,[21] Copyright 1984 American Chemical Society.)

being observed. For example, at the excitation wavelength (380.14 nm) where B[*a*]P was excited, the feature for B[*k*]F was observed; likewise the B[*k*]F fluorescence spectra, excited at 378.94 nm showed features of B[*a*]P. However, as can be seen from the spectra, the emission lines are sufficiently sharp to allow for identification of the different components in the mixture. Similarly, all the components in a mixture consisting of six mono-, two di- and three tri-alkylated benz[*a*]anthracenes were shown to be unequivocally identified.[21] The technique can therefore be seen to yield isomer-specific detection of samples, essential in the characterization of hazardous wastes.

However, a notable disadvantage of the Shpol'skii experiment is that the choice of matrix is not always obvious. A given compound or a class of compounds may have only a few matrices where the Shpol'skii effect may be observed. Secondly, some compounds may photodecompose in a Shpol'skii matrix. However, wherever applicable, MI fluorescence spectroscopy, utilizing laser-excited site selection (LESS), has been extremely useful in toxic waste evaluation, prompting the remark that one can "Do more with LESS."[21]

4.1.3 Matrix Isolation/Electron Spin Resonance Spectroscopy

As free radicals play an important role in atmospheric processes, it can only be expected that ESR spectroscopy would be a useful tool for these studies. The reactive

free radicals can be trapped in the inert matrix and then studied using ESR.

The matrix is deposited on sapphire or copper block substrates and the cold finger then introduced into the microwave cavity for ESR measurements. The unstable radical species survive in the inert matrix, on which ESR studies are performed. Details of the matrix isolation/electron spin resonance (MI/ESR) set-up and experimental procedures can be found in treatments on this subject.[14,22] In experiments where MI/ESR is used for atmospheric studies, CO_2 again turns out to be a useful matrix. Water (or D_2O), which are avoided in IR experiments, serve as a useful matrix for ESR studies. Oxygen, being paramagnetic, must be avoided in the matrix, or else it can interact with the deposited free radicals causing significant line broadening, something which the MI technique set out to eliminate in the first place! The first attempts of Snelson[12] did not yield useful spectra, essentially because the sampling method adopted then, which was to simply freeze out the air sample on to the matrix substrate, incorporated O_2 in the matrix.

Mihelcic et al. obtained MI/ESR spectra of free radicals by trapping them in CO_2 and H_2O matrices.[23,24] Oxygen was eliminated by maintaining the cold finger at liquid-nitrogen temperatures. In these experiments, care was taken to minimize the collisions of the sampled radicals with any of the surfaces of the sample compartment other than, of course, the cold finger. This was achieved by having the sampled air form a gas jet that concentrates around the cold finger. In early experiments,[23] the CO_2 and H_2O present in the sampled air were used as the matrix. However, it was soon realized that the trapping efficiency was low in such experiments and depended on the H_2O concentration, which was variable in the troposphere. They ensured a stable and a large collection efficiency by deliberately adding water during the matrix deposition. In later experiments, they showed that the use of D_2O yielded ESR spectra with smaller linewidths than those obtained with an H_2O matrix.[24]

Figure 15 shows the ESR spectra of free radicals, NO_2, NO_3, HO_2, and CH_3COO_2, trapped in H_2O and D_2O matrices.[24] The spectra in the D_2O matrices are

Figure 15 MI/ESR spectrum of common atmospheric radicals trapped in H_2O (upper trace) and D_2O (lower trace) matrices at 77 K: (a) NO_2, (b) NO_3, (c) HO_2, (d) CH_3COO_2. (D. Mihelcic, A. Volz-Thomas, H.W. Patz, D. Kley, M. Mihelcic, 'Numerical Analysis of Electron Spin Resonance Spectra from Atmospheric Samples', *Journal of Atmospheric Chemistry*, **11**, 275 (1990), Figure 1, with kind permission from Kluwer Academic Publishers.)

clearly sharper, resulting in greater sensitivity, and also allow for the identification of those radicals that show a characteristic hyperfine structure.

Using the experimental procedures described above, Mihelcic et al. studied the diurnal variation of NO_2 and RO_2 (total peroxide concentration). Their studies showed that the concentrations of NO_2 and RO_2 were anticorrelated and that the nighttime RO_2 concentration hardly differed from those obtained during the day. In another experiment, they also measured the vertical concentration profiles of NO_2 and RO_2 over altitudes ranging from 1 to 6 km. Using a least-squares spectral analysis algorithm, they showed that small amounts of HO_2 could be detected in the presence of a manyfold excess of NO_2 and other peroxy radicals. HO_2 and CH_3COO_2 radicals in tropospheric samples were shown to be detected at concentrations up to 40 pptv.

Being reactive species, free radicals play a very important role in the chemistry of the atmosphere and the MI/ESR technique provides a powerful technique with which to study them.

4.2 Study of Reaction Intermediates

To understand the chemistry and the various dynamic processes in the atmosphere, it is important not only to identify and quantify the different species present, but also to elucidate the important chemical reactions that they manifest. Many atmospheric reactions are photochemically driven processes involving reactive species. MI is a technique ideally suited for the study of such process as the following examples will show. The examples cited here are only representative and are not an exhaustive compilation.

As an example of the use of MI for the study of reactive species, some of the work pertaining to stratospheric ozone depletion is described. In this context, it is relevant to briefly review some of the chemistry involving ozone loss due to halocarbons.

Depletion of stratospheric ozone has been linked to the introduction of synthetic CFCs into the atmosphere, such as CF_2Cl_2 and $CFCl_3$. These CFCs are photolyzed in the upper regions of the atmosphere at altitudes of 20–40 km, leading to the formation of atomic chlorine (Equations 2 and 3):[25]

$$CF_2Cl_2 \longrightarrow CF_2Cl + Cl \quad (2)$$

$$CFCl_3 \longrightarrow CFCl_2 + Cl \quad (3)$$

An extensive catalytic chain reaction then occurs which depletes the O_3 concentration, (Equations 4 and 5):[26]

$$Cl + O_3 \longrightarrow ClO + O_2 \quad (4)$$

$$ClO + O \longrightarrow Cl + O_2 \quad (5)$$

Equation (5) regenerates atomic chlorine and the cycle is resumed. (The atomic oxygen, involved in Equation (5), is a trace constituent in the stratosphere and is produced by the photodecomposition of molecular oxygen.) The (ClO, Cl) chain therefore leads to a net ozone-loss reaction (Equation 6):

$$O_3 + O \longrightarrow 2O_2 \quad (6)$$

An alternative pathway is Equation (4) followed by Equation (7):

$$ClO + ClO \longrightarrow 2Cl + O_2 \quad (7)$$

Here again a (ClO,Cl) chain is involved and the net reaction is given by Equation (8):

$$2O_3 \longrightarrow 3O_2 \quad (8)$$

(Only the overall stoichiometry has been shown in Equation 7. As discussed later, the reaction actually proceeds through the intermediacy of Cl_2O_2 and ClO_2.) In this discussion, only reactions involving Cl have been shown; in reality a number of species such as OH, Br, and NO undergo reactions similar to Equations (4), (5), and (7), and play a significant role in ozone depletion.

From the above reaction scheme, it is clear that ClO is an important molecule in ozone depletion processes. Measurements have shown an increase in the ClO concentration over the polar stratospheric regions. It is therefore important to study the reactions of ClO with other species present in the atmosphere, so that the fate of the halogen monoxides in the atmosphere can be understood.

One such reaction is that between ClO and NO_2 to form chlorine nitrate. This reaction is important where the NO_2 concentration is high (Equation 9):

$$ClO + NO_2 + M \longrightarrow ClONO_2 \quad (9)$$

(In this reaction, M is a third body that removes the energy of the complexed species and stabilizes it.) The chlorine nitrate is expected to photolyze only slowly in the UV. This reaction would tie up the ClO, by converting it into the less active $ClONO_2$, referred to as a reservoir molecule. Equation (9) would therefore lead to a decrease in ozone depletion. However, there were speculations that this reaction may also produce a photolytically active *isomer* of chlorine nitrate, that may counter the reservoir effect. It was therefore important to study whether isomers of chlorine nitrate are produced by Equation (9). Burrows et al.[27] addressed this problem using MI/IR spectroscopy, where they studied the reaction between ClO and NO_2 by photolyzing flowing mixtures of Cl_2, Cl_2O, and NO_2 and trapping the reaction product in an

N_2 matrix. The following Equations (10–12) were driven during photolysis:

$$Cl_2 + h\nu \longrightarrow 2Cl \quad (10)$$

$$Cl + Cl_2O \longrightarrow ClO + Cl_2 \quad (11)$$

$$ClO + NO_2 + M \longrightarrow \text{product} \quad (12)$$

The find product formed in these reactions was then trapped in a nitrogen matrix and the IR spectrum of this product was compared with synthetically produced $ClONO_2$. It was observed that the product spectrum agreed well with the spectrum of synthetically produced $ClONO_2$ and no extra features were seen that could be assigned to an isomer of chlorine nitrate. It was therefore concluded that Equations (9) and (12) do not give rise to any isomer of $ClONO_2$. The hypothesis of the existence of a photochemically labile isomer of chlorine nitrate that could alter the ozone depletion scenario was therefore discarded.

In environments where NO_x abundances are low, the formation of chlorine nitrate (Equation 9) may be unimportant and alternate reaction pathways for ClO may dominate. Where the ClO concentrations are high, the self-reaction (Equation 7), may be significant. Such conditions appear to exist in the stratosphere over Antarctica. Although the net products are Cl and O_2, Equation (7) is believed to occur through the intermediacy of Cl_2O_2 and ClO_2 (Equations 13–15):

$$ClO + ClO + M \longrightarrow Cl_2O_2 \quad (13)$$

$$Cl_2O_2 + h\nu \longrightarrow Cl + ClOO \quad (14)$$

$$ClOO \longrightarrow Cl + O_2 \quad (15)$$

The species produced in the above reactions, Cl_2O_2 and ClO_2, have been the subject of a number of MI studies.

The structure, spectroscopy and reactions of the dimer, Cl_2O_2, have been studied in great detail. Following these studies, it was found that the ClO dimer exists in three isomeric forms (structures **(1–3)**):[28–31]

Dichlorine peroxide
(1)

Chloryl chloride
(2)

Chlorine chlorite
(3)

The most stable of these forms were structures **(1)** and **(2)**, which were of comparable energy, whereas structure **(3)** was the least stable. Johnsson et al.,[28] Jacobs et al.,[29] and Cheng and Lee[30] trapped the ClO dimers in an argon matrix and showed that these forms can photochemically interconvert before eventually decomposing to yield the products, O_2 and Cl as given in Equation (7). These studies also established the different photolysis channels of these species, information that was required to establish the fate of the ClO dimer in the atmosphere.

Likewise, ClO_2 has also been the subject of MI investigations.[32,33] Two different structures are possible for this species, OClO and ClOO. Both these isomers play an important role in stratospheric chemistry. The species ClOO is believed to be the primary photolysis product of ClOOCl, which then eventually dissociates to yield Cl and O_2, whereas OClO is suggested as an intermediate in reactions involving ClO and BrO. Muller and Willner[32] isolated both these isomers of ClO_2 in argon and neon matrices and studied their vibrational and electronic spectra. They also showed that OClO, when irradiated with a medium-pressure Hg vapor lamp ($\lambda \geq 395$ nm), converted to ClOO. The MI studies described above[28–33] therefore revealed the intricate details of Equation (7).

It may be recalled that an analysis of the upper troposphere using MI spectroscopy indicated the presence of carbonyl halides (section 4.1.1). The carbonyl halides were believed to be formed by the oxidation of halocarbons in the troposphere. In an effort to understand this oxidative process, MI studies were conducted to probe the reaction of oxygen atoms with halocarbons. Schriver et al.[34,35] have studied the reactions of compounds such as CCl_3F (Freon 11) and CH_3Cl with oxygen atoms produced by a photolytic decomposition of ozone. Among other products, they observed the formation of carbonyl halides such as COFCl, which was one of the species identified by Wilson et al.[15] in their analysis of the upper tropospheric samples. The experiments of Schriver et al. mimicked the oxidation of the halocarbons in the troposphere.

MI spectroscopy has been used in elucidating a number of these reactions to understand the atmospheric processes.

5 CONCLUSIONS

The technique of MI in conjunction with IR, fluorescence, and ESR has been used to address problems in atmospheric chemistry. Trace constituents in tropospheric and stratospheric samples have been measured, information that has proved useful in atmospheric modeling. Air samples from nearer to the earth's surface have also been analyzed to estimate chemically hazardous materials that can potentially affect the local ecology of a place. The technique of GC/MI/FTIR used for these analyses is particularly useful for isomer-specific detection of chemically hazardous materials. In these applications, GC/MI/FTIR even scores over other more sensitive techniques, such as MS. MI has also been used to study the structure,

spectroscopy, and chemistry of reactive species that play an important role in the chemistry of the atmosphere.

ABBREVIATIONS AND ACRONYMS

Current concepts for optical gas sensors are reviewed. Different approaches for gas sensing such as intrinsic and extrinsic, direct and indirect sensing were taken into consideration. For each sensing approach reviewed here, a short principle description and recent applications are given. Several aspects governing the enrichment of gaseous analytes in sensitive layers are also discussed briefly.

1 INTRODUCTION

The requirements of industry and legislation take advantage of the qualities of chemical sensors and especially fiber optics and/or planar waveguide transducers, using their capability to continuously report changes of a physical parameter or the concentration of an analyte and the sensor's ability to work reversibly. Industry discovered that chemosensors could be used for applications in process control, work place monitoring, and to follow legislation which requires threshold values for air, water, and industrial production to be met. Thus, demand for sensors has increased. These devices combine the properties of physical sensors (transducer) with the advantages and problems of chemical sensitive layers, by being responsible for the special properties of chemical sensors.

In the following, the properties of such optical sensors are discussed, they are classified according to certain characteristics and then the peculiarities of chemical sensing layers are considered. Since the definitions and general descriptions of sensors have been given in many reviews and books in recent years, just some of the special considerations regarding the optical chemical sensors applied to detect gases are given here. The main topics are the discussion of the chemical sensing layers and their present status of suitability, recent applications, and some trends in development and application to real-life situations in addition to modern analytical tools.

1.1 General Properties of Optical Sensors

An ideal sensor is sensitive, allows remote sensing and analysis in real-time, is economically priced, robust, reliable, cheap in maintenance, miniaturized, and simple to handle. Furthermore an ideal sensor is selective, has a high operational stability, has a wide dynamic range, and shows no drift of the baseline. Whereas the first of the mentioned prerequisites of an ideal sensor nowadays can be fulfilled by several transduction principles, the latter represent the remaining challenges in the field of chemical sensing. Most of these named restrictions are caused by the limited properties of the sensing element or sensitive layer.

One approach to overcome the limited selectivity of chemosensors is the application of chemometrics or pattern recognition.[1,2] However, these techniques often require defined boundary conditions, which unfortunately are seldom found outside the researcher's laboratory. This explains why, besides the optimization of the transduction principles, great efforts are taken in order to find the ultimate sensitive layers.

Light interacting with matter can yield a lot of different information about conditions of matter at high speed. Absorbance, luminescence, polarization,

interference, time, and wavelength (frequency), to name some examples, are measurements which can be interrogated by optical techniques. Optical sensors are generating increased interest due to several advantages such as remote sensing capabilities, no interference by electric or magnetic fields, and use in a wide area of applications, e.g. medical diagnostics.[3–5] Due to this growing interest in optical sensors, a large number of publications and review articles have been published. Therefore it is not possible, or the intention, to give here a complete overview of this wide and growing area of fiber optic and waveguide gas sensors. Accordingly, this article is restricted to certain aspects and new developments have not been reviewed in detail up to now. Therefore we want to emphasize that nonquotation of a paper does not give any judgement about its quality. For a detailed survey, one should refer to the volumes of the monograph *Chemical and Biochemical Sensors* edited by Göpel et al.,[6] which also gives a detailed insight into optical sensors.[6] A review covering chemical sensors from 1 December 1993 to 30 November 1997, with more than 900 references, was published recently.[7] Fiber optic sensors (FOS) are well represented by several monographs[8–12] and reviews.[13–17] Additionally, a detailed overview of infrared (IR) FOS is given by Saito and Kikuchi.[18] The development of liquid core optical fibers is discussed by Altkorn et al.[19]

Thus we will focus on certain techniques of optical gas sensors such as devices like surface plasmon resonance (SPR), planar waveguide sensors, FOS, and reflectometric interference spectroscopy (RIfS). Only recent developments in gas sensing will be discussed here.

1.2 Classification of Optical Sensors

Besides the technique (SPR, FOS), optical sensors can be classified by their waveguide optics and the analytical way to detect the analyte and the modulated parameter of light leading to a three-dimensional classification.[16] Whereas two dimensions, namely the detected parameter of radiation and the waveguide optics, are defined by the transduction principle and set-up of the device, the third axis is defined by the interaction the analyte experiences in the sensitive layer (Figure 1). We will not follow the scheme represented here strictly, but we consider it as a useful tool to classify the different methods, approaches and optics in the overall picture of optical sensors. A more detailed discussion of the following explained terms, which are used to classify the different types of FOS, is given by Boisdé and Harmer[9] and Potyrailo et al.[16]

In general, fiber optical and planar waveguide sensors use the same principle; they guide electromagnetic radiation by internal reflectance. They differ in geometry and in fields of application. Therefore, in the following,

Figure 1 Classification of optical sensor systems with respect to the effect on or by radiation, the transduction principle and the properties of the sensitive layer.

fiber optics and planar waveguide structures will be used synonymously and called waveguides in general. The first are in many cases preferably used to just transport radiation. Both can be applied to monitor influences on this guided radiation, in addition. Accordingly, in the figure both types are marked on one of the axes. Additionally, optical sensors can further be distinguished by the terms *extrinsic* or *intrinsic*. In extrinsic sensors, radiation is just transported by the waveguide, is modulated outside the waveguide, and will re-enter the waveguide to be re-transported to the detector. The waveguide is simply used to transport the light to the sampling point and from there to the detector. In intrinsic optical sensors the light is not intended to leave the light-guiding structure to be modulated, rather the light-guiding structure itself represents the sensing element.

Influence on radiation can either cause a change in signal height, a shift in absorption maximum (frequency), a change in phase by shift in superposition of partial beams of radiation, a shift in the state of polarization, or a change in the time domain.

Direct detection is defined by the measuring of direct spectroscopic properties of the analyte or the sensitive layer influenced by the analyte, whereas *indirect* detection is defined by the detection of an analyte interacting with an additional reagent. The terms passive or reactive detection are used in the literature as well. Indirect detection often gives the opportunity to enhance the selectivity, but, on the other hand, further obstructions as effective immobilization or bleaching of a dye may

occur. The large amount of papers dealing with indirect detection is reflected by the efforts taken to find new selective chromophores,[20,21] a collection about several applications and frontiers in analytical chemistry, sensor technology and the importance of near IR dyes herein is given in Daehne et al.[12]

In the following text, first principles of operation of planar waveguide or FOS are given, then the principles of interaction between sensitive layer and analyte are discussed. Next, some applications are discussed for selected optical transduction principles.

2 FUNDAMENTALS

2.1 Aspects of Sensing in the Evanescent Field Region

Evanescent wave sensors are devices for the detection of refractive index changes of the sensitive layer n_{sl} in contact with the waveguide, thus frequently called microrefractometers. This changes of n_{sl} may be caused simply by sorption or by a chemical reaction. The sensitive layer is hereby a component of the light-guiding element, which can be a planar waveguide or fiber optics. The concept of intrinsic sensing is demonstrated in Figure 2 and will be discussed in a qualitative matter using FOS. Small diameter (<1 μm dependence on wavelength of guided radiation) of a waveguide results in monomode properties, larger diameters allowing multimode operation. For a more detailed discussion see Göpel et al.,[6] Wolfbeis[8] and Boisdé and Harmer.[9]

The properties of optical fibers depend on their numerical aperture and the critical angle of total reflection. Both

Figure 2 Principle of intrinsic sensing. (a) Evanescent field in the sensitive layer; (b) d_p depending on different experimental conditions (α, α^*, λ).

of these depend on the refractive index of the core n_{core} and cladding n_{clad} of the fiber. Additionally, the numerical aperture depends on the refractive index of the surrounding medium as well. At each spot, where the guided light meets the interface between the core and the cladding, an electromagnetic field will be present on the side of the cladding, respectively, in the sensitive layer. This field is the so-called evanescent field, which penetrates into the cladding and the sensitive layer, depending on the refractive indices of the core and the cladding, respectively, the sensitive layer (n_{clad}, n_{sl}), and on the incident angle θ at the core/cladding interface. The penetration depth d_p can be calculated with Equation (1):[9]

$$d_p = \lambda \quad 2\pi n_{core} \quad \sin^2\theta - \left(\frac{n_{core}}{n_{clad}}\right)^{2} \quad ^{-0.5} \qquad (1)$$

Analyte molecules sorbing into the sensitive layer will change n_{sl} (if $n_{analyte}$ and n_{sl} differ) and influence the evanescent field. This means that the sorbed analyte molecules modulate the light transmission properties of the fiber, which can be detected by a spectrometer or photodiodes.

Advantages of this intrinsic sensing concept are:

- no interrupted optical path, therefore an effective light budget;
- distributed sensing;
- many different transducers available, direct and indirect sensing possible;
- if $d_p < d_{sl}$, no cross-interference with substances outside the sensitive layer.

The parameters such as numerical aperture of the fiber, monomode or multimode fiber, wavelength, and thickness of the sensitive layer[22] must be chosen with care, in order to ensure that the penetration depth d_p will not become greater than the thickness of the sensitive layer. For applications in the middle IR region, this aspect is of special interest, since d_p is proportional to wavelength and d_p is increasing considerably in the region of the critical angle.[22] An increase of the sensitive layer's thickness would increase diffusion times of the target molecule and hence decrease the sensor's performance.

2.2 Sensitive Layers

In recent years a lot of different materials have been investigated in order to enhance sensitivity and selectivity of the sensitive layers. A new approach to mimic antibodies is imprinted polymers,[23,24] whereby the most promising examples achieving specific detection were demonstrated in liquid phases. Additionally, cyclohexapeptide,[25] porphyrins,[26,27] phthalocyanines,[28,29] tailored polymers,[21,30–32] sol-gels[33–36] and organically modified

silicates[37,38] (ormosils) were the focus of several publications.

2.2.1 Aspects Influencing Sorption

It will be of importance to obtain highly selective matrices, which are used to enrich the analyte molecules or to bind receptor molecules like dyes. For in doing so a profound understanding of the sorption of analytes in polymeric, sol-gel or other layers, which will be referred to as sensitive layers in the following text, is necessary. The sorption of an analyte molecule into a sensitive layer can be separated schematically in at least three processes:

1. adsorption onto the surface of the sensitive layer;
2. phase transition and diffusion from the outer surface into the sensitive layer's bulk;
3. subsequent physical interactions with the sensitive layer.

Another process will take place, if the analyte molecule has chemical interactions with certain reaction sites present in the sensitive layer (Figure 3).

2.2.2 Boiling Point Dependency of Sorption

Sometimes the dependence of sorption on boiling point is misinterpreted as size selectivity of the sensitive layer. However, the energy needed to cause the phase transition from the adsorbed state to the gas phase increases with lower vapor pressure. If no real size-selective properties of the matrix or sensitive layer exist, e.g. as found in zeolites[39] or polyimides,[40] the sorption of analytes for direct detection can be described in the following way.

A scale for the enrichment of a compound i is the partition coefficient f^i, which is the ratio of the concentration of the analyte molecule in the sensitive layer c^i_{sl} and the concentration in the gas phase c^i_g as shown in Equation (2):

$$f^i = \frac{c^i_{\mathrm{sl}}}{c^i_g} \tag{2}$$

Nonpolar analytes interact with the chosen sensitive layer in a similar way. Then f^i will increase with decreasing vapor pressure. Taking Picet–Trouton's rule, which is valid in a homologous series, the boiling point (T_{b}) dependence of f^i for the analyte i can be estimated[41] according to

$$\log f^i = 4.8\frac{T_{\mathrm{b}}}{T} - 4.8 + 0.43\frac{\Delta S^{0,\mathrm{m}}}{R} \tag{3}$$

where $\Delta S^{0,\mathrm{m}}$ is the standard entropy of mixing. Equation (3) shows that the vapor pressure of a substance is governing the enrichment of a substance within a sensitive layer, if no subsequent chemical interactions occur.

2.2.3 Further Factors Affecting Enrichment

Attractive forces between analyte molecules and the sensitive layer can cause additional effects. Besides Coulomb forces, permanent dipole–dipole, induced dipole–dipole, and dispersion forces are discussed. In addition, hydrogen bonds will increase the interaction between analyte and sensitive layer. For these kinds of interactions the chemist's rule of thumb "like dissolves like" may be used to choose which sensitive layer is an appropriate choice for a certain analyte, in order to achieve high partition coefficients.

Furthermore, the analyte molecule may undergo chemical reactions at reaction sites present in the sensitive layer (see steps 3 → 4 in Figure 3) enhancing the sensitivity and selectivity. A typical example of such a reaction is the reaction between an acidic or basic molecule and an indicator dye entrapped in the sensitive layer.

Figure 3 Sorption steps of an analyte molecule: (1) adsorption onto sensitive layer; (2) phase transition and diffusion from the surface into the bulk; (3) subsequent physical interactions; (4) diffusion to reaction site (physically or chemically trapped in the polymer) with chemical interaction.

3 REFLECTOMETRIC INTERFERENCE SPECTROSCOPY

3.1 Introduction

RIfS was described by Gauglitz et al.[42] and has similar sensing capabilities as quartz microbalances (QMBs). Both methods can detect the enrichment of volatile organic compounds (VOCs) or other analytes in polymer matrices. Whereas QMBs detect in principle the mass uptake of the sensitive layer, RIfS detects the change of the optical path length, which can be measured directly. With respect to the terminology of section 2.2, RIfS

Figure 4 (a) Measurement set-up consisting of a white light source, fiber optics, transducer, and a diode array spectrometer; (b) typical reflectance spectra and the corresponding change of the optical pathlength *nd*.

is an extrinsic FOS system detecting modulations in the wavelength region, and allowing direct and indirect analyte detection.

3.2 Principle of Reflectometric Interference Spectroscopy

Spectral interferometry measures the interference pattern caused by the superposition of two reflected partial beams at parallel interfaces of a thin layer. Spectral interferometry depends on the refractive indices of the film, the thickness of the film, the wavelength (preferably in the optical region 400–700 nm), and the angle of incidence of radiation.

The principle set-up depicted in Figure 4 consists of a white light source, Y-fibers, the sensing element, and a diode array spectrometer. The signal is measured relative to a coated (noncoated) substrate I_r (I_{ref}), according to Equation (4). I_0 represents the blank or zero signal.

$$I = \frac{I_r - I_0}{I_{ref} - I_0} \tag{4}$$

If an analyte sorbs into a polymer film, the film will change its optical thickness *nd*, where *d* is the physical thickness and *n* the refractive index of the sensitive layer. A more detailed description of the principle and evaluation of RIfS is given by Kraus and Gauglitz.[43] The system was adapted to multianalyte sensing by Seemann et al.[44] A miniaturized RIfS set-up, where the white light source was replaced by four light emitting diodes, and the spectrometer was replaced by a simple photo diode, was presented recently.[45] Because of the coherence condition of white light and the interference condition, the film thickness of that layer, where the sensitive coating builds up the interference layer, has to range between 300 nm and 30 μm. However, if the sensitive coating is attached to a solid SiO_2 layer acting as basic interference layer, even sorption on to monolayers can be investigated.[25,46]

3.3 Applications

The response of a polymer like poly(dimethylsiloxane) (PDMS) versus several VOCs as *n*-pentane to *n*-octane or chlorinated hydrocarbons is described by Gauglitz et al.[46] Films thinner than 1 μm yield response times less than 1 s. For tetrachloroethene a detection limit in the ppm range was found and the sensor response was linear up to 10 000 ppm. Since the PDMS-based sensor showed high cross-sensitivities against the mentioned VOCs, it became obvious that a multisensor set-up and subsequent chemometrics[47] must be used, in order to overcome this limitation in the analysis of mixtures. Artificial neuronal networks[44] and partial least-squares regression methods[48] were applied to discriminate binary or ternary VOC mixtures. The sorption behavior of different VOCs in five different polymer-based sensitive layers with and without relative humidity was investigated.

Based on these considerations, great effort was made to find sensitive layers with higher selectivities. For

cyclohexapeptides, which proved to be highly selective for certain amino acids in aqueous phase,[49] it could be verified that the analyte's permittivity plays a major role besides the analyte's vapor pressure for the resulting sensitivity. Similar selectivities to those in the aqueous phase towards different VOCs,[25] could not be found in the gas phase.

The detection of basic or acidic substances with optic gas sensors is usually accomplished by physical or chemical entrapment of an indicator dye in a sol-gel or polymer matrix. As long as the optical properties of the indicator dye will not change in a unexpected way, covalent linking of the dye is advantageous, since diffusion or leaching of the dye can be prevented. One major drawback of indicator dyes is due to photobleaching,[13] which limits the operational stability of the sensor. pH-responsive polymers allow the dyeless optical detection of basic or acidic substances by covalent incorporation of acidic or basic functional groups in the polymer matrix. Analyte-induced deprotonation of these functional groups leads to additional uptake of water by the polymer. Using a modified polysiloxane[32] with carboxylic acid end-groups, detection limits below 200 ppb could be determined for ammonia. The signal decrease was 30% in 68 days. During this time period the sensor was continuously exposed to white light and synthetic air (20.5% O_2 in N_2). A dye doped sol-gel layer exhibited a 40% decrease of the signal under identical boundary conditions within 10 h. Drawbacks were the long response time and the influence of relative humidity on the sensor's signal.

In principle, achieving chiral discrimination by gas sensors is more difficult than by gas chromatography (GC), because the sensor uses only one ''theoretical plate'' (one adsorption/one desorption step). In contrast, using GC discrimination typically results from thousands of successive adsorption/desorption equilibria. Nevertheless Bodenhöfer et al.[50] successfully demonstrated the separation of optical enantiomers using QMB and RIfS. *S*- and *R*-octyl-Chiralsil-Val were used as selective coatings, and the enantiomers of *N*-trifluoroacetyl-alanine-methylester (TFA-Ala-OMe) were used as analytes. Both sensors, the *S*- and *R*-type, showed identical signals when exposed to the racemic mixture of TFA-Ala-OMe; however, there was little increase in signal height for the equivalent isomer.

4 FIBER OPTIC SENSORS

The term opt(r)ode is commonly used to name sensor systems, wherein optical fibers are taken. Both terms were defined by Lübbers. Optode[51] is derived from the Greek, meaning the ''optical path'', whereas optrode[52] stands for ''optical electrode''. Since the applications for FOS, especially indirect FOS, are extensively covered in the literature (see section 1), the theory will only be handled in brief. Only recent applications will be considered. A description of interferometric noise is given by Jin et al.[53,54] and may prove useful for the design of a particular fiber optic gas sensor, since interference between signal radiation and reflected radiation can cause signal fluctuation in the output, which can limit the performance of the sensing system. By the application of gas-permeable membranes,[55] FOS are easily adapted for liquid sensing.

4.1 Extrinsic Sensing Applications

4.1.1 Extrinsic Direct

Dasgupta et al.[56] presented a new long-path optical transmission cell for fiber optic absorbance measurements, which is a liquid core fiber optic waveguide. The cladding of this waveguide is simply a hollow polymer tube. Since the polymer's refractive index is <1.333, water can be used as the core of the fiber. The fluoropolymer used has a three times higher gas permeability with respect to poly(tetrafluoroethylene)-type Teflon®, therefore the fiber shows potential for chemical sensing in the liquid and gaseous phases. A FOS for smoke measurements was presented by Matias et al.[57] The sensor works based on the following principle: diesel engine particulates get stuck on a gluing surface of a white tape, changing the diffuse reflectance of the tape's surface. Response times in the range of 0.1 s were reported. Different types of extrinsic sensing configurations are schematically shown in Figure 5.

4.1.2 Extrinsic Indirect

Cardoso et al.[58] described a highly sensitive fluorescence-based extrinsic indirect FOS for the detection of atmospheric H_2S in the ppb_v range. A drop of

Figure 5 Different measurement configurations for extrinsic fiber optic sensing. (a) Indirect, end of fiber; (b) direct, end of fiber; (c) indirect, transmission; (d) extrinsic, direct, transmission.

alkaline fluorescein acetate solution is suspended in a flowing air sample stream. As H_2S in the sample is collected by the alkaline drop, it reacts rapidly with the fluorescence dye, resulting in a significant decrease in fluorescence. Tabacco et al.[59] modified an indirect CO_2 sensor with a gas permeable membrane for measurements in seawater. The sensor exhibited a reversible working range between 200 ppm and 1000 ppm PCO_2. Selective opt(r)ode membranes were presented by Spichiger-Keller[21] for the detection of ethanol and CO_2 in bioreactors.

4.2 Intrinsic Sensing Applications

The principle of sensing in the evanescent field region has already been shown in Figure 2. Additionally, typical sensing configurations are depicted on Figure 6. In the normal fiber arrangement, part of the cladding is removed to allow the evanescent field to be directly in contact with the sensitive layer either in a transmission mode (Figure 6a) or in reflection (Figure 6b). Another approach is to bend the fiber at the region coated with the sensitive layer (Figure 6c). This may lead to a significant increase of the sensitivity;[60,61] however, the system becomes sensitive to mechanical disturbance.

4.2.1 Direct Intrinsic

A porous sol-gel layer[36] was used in order to detect analyte-induced changes of the refractive index. The detection limits of different alkanes and halogenated hydrocarbons were in the range between 0.6% and 25%. An ozone sensor was described by Potyrailo et al.[62] with good stability over a 2-month period of investigation and a linear response between 0.02 vol.% O_3 and 0.35 vol.% O_3. The response proved to be reversible with a time constant of 1 min. It is noteworthy that these investigations were performed in the near ultraviolet (UV) region (at 254 nm), whereas most published investigations for evanescent field sensing are either in the visible or near and mid IR wavelength region. Attenuated total reflection IR/FOS[18] can be classified as direct intrinsic sensors as well.

Figure 6 Different fiber optic evanescent field sensing configurations: (a) sensitive layer, side on fiber; (b) like (a) with mirror attached, end on fiber; (c) bent fiber.

A multipoint sensor system is described in Stewart et al.[63] for methane detection along a long fiber using optical time-domain reflectometry (OTDR).[64] A short light pulse is coupled into the fiber and transported by total internal reflection. A certain amount of the light will be back-scattered at the fiber's end and can be recorded by a fast detector resolved with time. This allows localization of any effect (laterally resolved) within the cladding of the fiber by the time delay between the excitation pulse and the received back-scattered signal (change in the effective refractive index at a point causes partial back-scattering of the guided radiation). This is a well-known technique to characterize fiber optic networks. An overview of the possible applications with direct and indirect signal modulation was recently given by Sensfelder et al.[65] One limitation of the OTDR technique is the loss of light guiding capabilities, if the refractive index change reaches such an extent that the out-coupling of radiation damps the propagating radiation. Thus no information can be obtained about effects beyond this point.

4.2.2 Indirect Intrinsic

An indirect intrinsic fiber optic evanescent field sensor based on near IR dyes was reported by Malins et al.[66] Methyl and ethyl derivatives of a 5-(4′-dialkylaminophenylimino)-quinolin-8-one copper(II) perchlorate complex were immobilized in a thin poly(vinyl chloride) matrix coated on an optical fiber with 600 μm diameter. Ammonia in the range between 10 ppm and 100 ppm was investigated. The sensor showed response (recovery times) of the order of 30 to 40 s.

UV-curable ormosils have been synthesized by the sol-gel method and used as sensitive layer for silica optical fibers.[31] The refractive index of the coating could be tailored in the range between 1.46 and 1.56. The sensitivity versus CO_2 could be enhanced by the introduction of amino groups into the polymer.

A humidity sensor based on a hydroxypropylcellulose film doped with Rhodamine B was presented by Taguchi et al.[60]

5 PLANAR WAVEGUIDE SENSORS

5.1 Introduction

An illustrative insight into the field of integrated optics (IO) and planar or slab waveguides is given by Göpel et al.[6] and Boisdé and Harmer.[9] IO comprises several benefits such as ruggedness, miniaturization, construction on a chip, high sensitivity, and remote sensing capabilities,

Figure 7 Different types of planar waveguides, where $n_1 > n_2, n_0$.

since IO parts can efficiently be linked to fiber optics. Planar waveguides are frequently used for intrinsic sensing in the evanescent field region by the use of grating couplers and polymers acting as sensitive layers. IO grating couplers were proposed by Tiefenthaler and Lukosz[67] in 1987.

Planar waveguides can be classified as a film waveguide (thin layer on top of a substrate) or a strip waveguide (often called a slab waveguide). A slab waveguide can be described in the most simple form as a dielectric layer with the refractive index n_1 matched in-between two layers, the substrate and the superstrate layer, with the refractive indices n_0, n_2, where $n_1 > n_0, n_2$. Some variations of the set-up of planar waveguide configurations are depicted in Figure 7.

Since a proper theoretical discussion of the influence of the waveguide structure is far beyond the scope of this review, we want to refer to the already mentioned monograph by Göpel et al.[6] and references therein. Shortly, the sorbed analyte will directly or additionally indirectly vary the refractive index of the sensitive layer, thereby either modulating the transmission of the guided light or reflectance properties of a grating. Usually the light source is a laser and will be coupled into the waveguide by a grating, a prism[68] or a gradient index fiber.[69] Chirped waveguide gratings[70] simplify the conditions to meet the coupling conditions. Several concepts of the IO refractive index sensing systems are described by Kunz.[71]

Another approach uses interference between two waveguide arms forming a Mach–Zehnder type arrangement.[72] One of the waveguide arms is coated by polymer or any other sensitive layer, the other is a reference arm. Reduction of propagation velocity in the first arm causes phase modulation of the signal monitored after reunification of both radiation pathways (see Figure 8).

5.2 Applications

An integrated optical absorbance sensor for the detection of trichloroethene and tetrachloroethene in the near IR wavelength region was described by Burck et al.[69]

As frequently applied in FOS, the incorporation of indicator dyes into a sensitive layer is used for the detection of acidic or basic analytes. An example is given by Brandenburg et al.[73] for the detection of ammonia. Bromocresol Green and Bromophenol Blue were immobilized in a silicone matrix. Concentrations less than 1 ppm were detectable with a dynamic range up to 20 ppm. Acidic gases were found to reduce the relative change in signal.

Iodine gas can be detected by the formation of charge-transfer complexes between iodine and phenyl groups, which were incorporated in a methylated glass film.[74] A linear response was obtained in the range between 100 ppb and 15 ppm, with response and recovery times less than 15 s.

A coupling wave optical waveguide was presented by Qing et al.,[33] which proved to be very sensitive versus H_2S. The feature of this sensor is that the one waveguide can be adjusted for light guiding and the other for sensing.

Figure 8 Mach–Zehnder arrangement with phase modulation of detected intensity.

Thin films of RbCl and AgCl were used as sensitive films on a planar optical waveguide to sense chlorine with a measurement range from 3 ppm to 1.5%.[75]

The properties of a nematic liquid crystal as a sensitive layer for VOCs were investigated by Drapp et al.[76] Therein it was demonstrated that the analyte-induced phase transition of liquid crystalline systems can lead to enhanced sensitivities and selectivities.

6 SURFACE PLASMON RESONANCE SPECTROSCOPY

6.1 Introduction

SPR spectroscopy is a frequently used technique in biosensor technology.[77] The great demand for a marker free transducer system is reflected by the appearance of commercially available systems like the Swedish Biacore AB, launching the first commercial SPR biosensor in the market in 1990. Another commercial SPR system was introduced by Texas Instruments (called TI-SPR-1) with bio- and chemosensing capabilities in liquid phases.[78] Liedberg et al.[79] pioneered SPR spectroscopy in the field of chemical sensors in 1983. However, the amount of publications concerning chemosensors is well below the amount of publications concerning the biosensor field. Forgenson and Yee[80] introduced the fiber optic evanescent field to SPR spectroscopy in 1993. Miniaturization and parallelization of the transducer can be achieved by integrated optic devices. The use of fiber optics and integrated optic devices would enhance the remote sensing capabilities, allow multiple component analysis and probably reduce the wide gap between the laboratory and field applications. A survey of trends in SPR was recently given by Homola et al.[81] With respect to the terminology discussed in section 1.2, SPR spectroscopy is a direct intrinsic sensing method.

6.2 Principle of Surface Plasmon Resonance

A plasmon wave is a collective excitation of the electron gas in a metal.[82] There exist two different kinds of surface plasmons depending on the excitation conditions, radiating and nonradiating surface plasmons. Whereas volume and radiating surface plasmons[83] have to be excited by UV light, nonradiating surface plasmons[84] can be excited by polarized visible light. The latter case exists for the applications given. No further distinction between the different kinds of the surface plasmons will be made in the following text.

The total reflection of light, occurring at a phase boundary (e.g. between the prism coupler and a metal film), is accompanied by the origin of an evanescent field, which penetrates the metal film. If the energy of the evanescent field is meeting the resonance condition for surface plasmon waves in the metal film, the reflected light will experience an attenuation. The metal film has usually a thickness of around 50 nm.[82,85] The surface plasmon wave is a resonant phenomenon that depends on the index of refraction and the thickness of the metal film, as well as on the index of refraction of the adjacent medium containing the analyte (and a sensitive layer, respectively). The resonance condition to excite a surface plasmon can be met by either varying the angle of incidence θ or wavelength λ of radiation.

SPR measurement techniques are based on the detection of modulation of the intensity,[79,86] the angle,[78,87,88] the wavelength, leaky modes[89] or by phase modulation of the reflected light.[90,91] The detection of the pure intensity, which is based on a measurement set-up with fixed angle and wavelength, is less desirable, since it cannot be determined whether the signal change is caused by a change of n or whether experimental errors are responsible. Common experimental methods are in principle based on angle or wavelength modulation. An elegant set-up for angle modulation, without any components in motion was accomplished by Melendez et al.[78] Wavelength modulation does not require moving instrumental components, simplifying the experimental conditions and enhancing reproducibility. A further method is based on the detection of the phase modulation.[90] Since surface plasmon waves can only be excited by transversal magnetic modes (plane of polarization parallel to the plane of incidence) excitation of surface plasmon waves will cause a detectable phase shift between reflected transversal electric (perpendicularly polarized) and transversal magnetic polarized light.

6.3 Measurement Set-ups

In contrast to the Otto type, which excites surface plasmons by visible light at the base of a prism with a short distance to a metal surface,[92] Kretschmann pursued another strategy.[93] The thin metal layer is directly coated on to the base of a dielectric. The plasmon is excited at the opposite surface of the metal film close to the analyte or a sensitive layer as demonstrated in Figure 9.

Figure 9 Typical Kretschmann configuration.

Figure 10 Set-up of a fiber optic SPR.

A modification of the Kretschmann configuration was described recently by Homola and Yee.[94] The use of two crossed polarizers with a 45° orientation to the plane of incidence and a phase retarder allow the detection of the surface plasmon as a peak, which may be advantageous if the usually detected resonance minimum is adversely affected by, say, an analyte-induced optical nonhomogeneity.

In the original set-up the high refractive index material was a prism, but it can also be the core of a fiber[80] or the window of a planar waveguide.[95] The fiber optic SPR set-up is simpler than the classical Kretschmann set-up. The prism and the ray trace is replaced by a Y-fiber optical waveguide as schematically shown in Figure 10. The reference spectra are recorded by measuring the reflectance spectra of the fiber with the bare metal film (without sensitive layer). No particular care needs to be taken wih regard to the coupling of light into the prisms. In contrast to the Kretschmann configuration, where just one reflection occurs, waveguide SPR increases the signal by taking advantage of multiple interactions along the length of the metal layer. Waveguide sensing devices are therefore simple, easy to handle, usable as probes or for remote sensing.

Integrated optical SPR sensors based on planar waveguides have several benefits: small size, ruggedness, the fact that multichannel sensors on a single chip are possible, with all this being combined with fiber optics remote sensing capabilities. A design tool for a multilayer set-up to calculate the transmission characteristics of planar waveguide SPR sensors is described by Harris and Wilkinson.[95] The device shown in Figure 11 demonstrates the multilayer approach.

A variant of the planar waveguide set-up was developed by Karlsen et al.[96] and Homola and Yee.[97] A measurement set-up with multicomponent chemical analysis

Figure 11 Scheme of a waveguide-based SPR configuration.

capabilities was proposed, based on a planar light pipe, which allows the reflectivity to be determined as a function of wavelength for a set of angles of incidence. The detection of phase shift between transversal magnetic and transversal electric polarized light was introduced by Nelson et al.[90] and has a high calculated resolution for Δn (0.5×10^{-6}), which could not be verified experimentally. Additionally, it must be noted that the experimental set-up for the detection of phase modulation amounts to as many as 21 components.

6.4 Applications

Since SPR spectroscopy detects changes of the refractive index, the sensitivity is not only governed by sorption effects, but in addition the difference between the refractive indices of the analyte and the sensitive matrix has to be taken into account.[98] Furthermore, the insufficient stability of the silver layer against oxidation or hydrogen sulfide[99] must be solved in order to achieve a high operational stability of the sensitive layer under real conditions. This is commonly achieved by the use of alkylthiols as self-assembled monolayers (SAMs). Niggemann et al.[100] obtained an operational stability of 3 months, with an identical sensitivity of the PDMS layer. The response time of the sensor was in the range of 2.5 s and the detection limit was estimated to be 15 ppm.

Abdelghani et al.[88,98] used a fluoroalkoxysiloxane polymer and alkythiol SAMs as well. The observed limits of detection for chlorinated hydrocarbons were still in the low percent range (C_2HCl_3, 0.3; CCl_4, 0.7; $CHCl_3$, 1; CH_2Cl_3, 2). However, coating the silver or gold layer will not solve all the problems, according to Schoenfisch and Pemberton.[101] They found that the sulfur–metal bonding is oxidized under ambient conditions. It was proposed that ozone is responsible for the observed oxidation process.

Besides the detection of VOCs with sensitive layers on polysiloxane bases, the detection of NO_x with porphyrin-based sensitive layers is described in several publications.[28,29,102] Zhu et al.[29] used a copper phthalocyanine Langmuir–Blodgett film to detect NO_x gas. The limit of detection was in the range of several ppm, with unacceptably long recovery times for a practicable sensor. A selective NO_2 was described by Ashwell and Roberts.[103] It exhibits few cross-interferences to 100 ppm SO_2, H_2S, Cl_2, CO, CO_2 and 10% deterioration after 1000 to 1500 adsorption/desorption cycles. Nikkitin et al.[102] described an experimental set-up that allows combination of surface-enhanced Raman scattering (SERS) and SPR to detect NO_2 (limit of detection < 4 ppm). The recovery time was reported to be longer than 300 s. Furthermore, it was noted that the

sensing effect of the pure gold film may exceed the signals of the phthalocyanine-coated layers. A recent publication describes the enhancement of the sensitivity using a dye (1,1′,3,3,3′,3′-hexamethylindodicarbocyanine iodide) which contains a strong absorption band centered in the dynamic range of the SPR coupling wavelength.[104]

Agbor et al.[105] investigated a polyaniline-based sensor versus NO_2 and H_2S with detection limits of 50 ppm. On to the silver layer a thin nickel layer was deposited (1 nm Ni on top of 50 nm Ag) in order to prevent other gas effects on the silver layer.

7 SUMMARY

The review intends to demonstrate that a large variety of optical transduction principles exist and these provide some solutions to different analytical problems. Most of them employ similar sensitive materials, proving that the quality of the sensing device in most cases depends on the properties of the sensitive layer rather than on the transduction principle chosen. Certainly in the future there will be some improvements in the optical properties of the different devices.

The main interest in recent years has been dedicated to sensing-material that is more stable, more selective, demonstrates better response times and is tailored to suit the application. In this area, new materials and new approaches will attract the most interest. Problem-solving that related especially to synthesized polymer films that combine stability and inertness with some selectivity by functional groups, while keeping their reversibility will be well worth the efforts of chemists. The first publications testing approaches with liquid crystals and polymer backbones, as well as using molecular imprinted polymers, demonstrate these trends.

Scanning the literature for new developments shows the need to combine knowledge in optics with skill in polymer chemistry in order to create improved sensor devices. This fact simply takes account of the fundamental idea of a chemical sensor containing (in addition to a physical sensor) a sensitive layer which takes care of the chemical interaction between the analyte and the sensor and determines the properties of the sensor system.

ABBREVIATIONS AND ACRONYMS

FOS	Fiber Optic Sensors
GC	Gas Chromatography
IO	Integrated Optics
IR	Infrared
OTDR	Optical Time-domain Reflectometry
PDMS	Poly(dimethylsiloxane)
QMB	Quartz Microbalance
RIfS	Reflectometric Interference Spectroscopy
SAM	Self-assembled Monolayer
SERS	Surface-enhanced Raman Scattering
SPR	Surface Plasmon Resonance
TFA-Ala-OMe	*N*-trifluoroacetyl-alanine-methylester
UV	Ultraviolet
VOC	Volatile Organic Compound

Since ancient times people have searched for ways to understand processes occurring in the environment, atmosphere or living organisms. Study of the gaseous trace compounds present may shed new light on chemical reactions taking place in the atmosphere or biochemical reactions inside organisms such as plants, animals and human beings. This article presents photoacoustic spectroscopy as a sensitive, on-line and noninvasive tool for monitoring the concentration of trace gases. Following a short introduction and a historic overview, attention is focused on the description of devices and equipment which determine the detection limits and selectivity. An overview is given of the current detection limits for photoacoustic detection. Applications are discussed with emphasis on environmental monitoring (in ambient air, car exhaust and stack gas emission), on medical applications and on biological applications (in postharvest physiology, plant physiology, microbiology and entomology).

1 INTRODUCTION

A gaseous molecule that absorbs electromagnetic radiation is excited to a higher electronic, vibrational or rotational quantum state. Generally, depopulation of this quantum state to lower lying states occurs either via fluorescence or collisions, the latter giving rise to a temperature increase of the gas due to energy transfer to translation. This nonradiative relaxation process occurs when the relaxation time can compete with the radiative lifetime of the excited energy levels. Radiative decay has a characteristic lifetime of 10^{-7} s at visible wavelengths as compared with 10^{-2} s at 10 μm. For nonradiative decay these values depend on the pressure (decay time τ inversely proportional to the pressure) and can vary strongly at atmospheric pressures (10^{-3}–10^{-8} s).

By modulating the radiation source at an acoustic frequency the temperature changes periodically, giving rise to a periodical pressure change which can be observed as an acoustic signal; in the gas phase the effect can be detected with a sensitive microphone.

Laser-based photoacoustic detectors are able to monitor trace gas concentrations under atmospheric conditions with orders of magnitude better sensitivity than conventional scientific instrumentation; in addition they are able to monitor noninvasively and on-line under dynamic conditions.

2 HISTORY

The photoacoustic effect was first reported by Alexander Graham Bell in 1880;[1] he discovered that thin discs emitted sound when exposed to a rapidly interrupted beam of sunlight. In a later experiment,[2] he removed the eye-piece of a commercial spectroscope and placed absorbing substances at the focal point of the instrument. The substances were put in contact with the ear by means of a hearing tube (Figure 1a and b) and he found "good" sounds in all parts of the visible and invisible electromagnetic spectrum of the sun.

Other publications on this phenomenon followed this first work; we mention here the works of Röntgen,[3] Tyndall[4] and Preece.[5] However, due to the lack of a quantitative description and the lack of a sensitive microphone, interest in the photoacoustic effect soon declined.

In 1938 Viegerov refined the photoacoustic technique for the first spectroscopic gas analysis;[6] hereafter Luft[7]

Figure 1 (a) The eye piece of a spectroscope is removed and substances are placed in the focal point of the instrument behind a slit. These substances are put in contact with the ear by means of a hearing tube.[2] (b) Sunlight is intercepted and aligned with a steering mirror (C, D), modulated with a chopper (B) and focused onto a glass bulb (A).[2]

measured trace gas absorption spectra with an infrared broadband light source down to the parts per million level.

By the end of the 1960s, after the invention of the laser, scientific interest increased once again. In 1968, Kerr and Atwood[8] utilized laser photoacoustic detection to obtain the absorption spectrum of small gaseous molecules. Due to the high spectral brightness of lasers and improved phase-sensitive lock-in techniques that amplified the acoustic signal, they were able to determine low concentrations of air pollutants. Kreuzer[9] demonstrated that it was possible to detect concentrations of e.g. 10^{-8} (10 parts per billion) of methane in nitrogen, using an intensity modulated infrared (3 μm) He-Ne laser. Patel et al. demonstrated the potential of the technique by measuring the NO and H_2O concentrations at an altitude of 28 km with a balloon-borne spin-flip Raman laser.[10] After this the photoacoustic effect was introduced into the field of trace gas detection with environmental, biological and medical applications.

3 DEVICES AND EQUIPMENT

3.1 Light Sources

With reference to the previous paragraph, lasers are not essential to operate photoacoustic gas detection systems. Although the spectral power density of broadband infrared light sources is orders of magnitude lower compared with lasers, their advantages are reliability and cost effectiveness. Infrared light sources in combination with various photoacoustic detection schemes are commercially available for trace gas detection at parts per million levels. Spectral selectivity is achieved by using FTIR (Fourier transformed infrared) spectroscopy in combination with spectral band filters in front of the photoacoustic cell; thus typically seven molecular gases can be detected simultaneously at the 1–100 ppm level.

The URAS gas analyzer of Hartmann & Braun uses a photoacoustic detection scheme which is able to detect a specific gas out of a multicomponent gas mixture avoiding cross interferences. In this instrument selectivity is achieved by comparing the direct absorption in a sample cell to that in a reference cell. After passing the sampling cells, each attenuated light beam enters a second detection cell filled only with the gas of interest (Figure 2); the detection cells are interconnected via a membrane connected to a capacitor. Since the dual beam is modulated the difference in acoustic energy reflects the difference in absorption and thus the concentration difference between sample cell and reference cell. The species under investigation enables the wavelength to be selected in such a way that all wavelengths at which absorption occurs are simultaneously active. When there is no spectral overlap from other gases, additional absorptions in the sample cell will not contribute to the acoustic signal; the light passes the

Figure 2 Infrared gas analyzer of Hartmann & Braun with photoacoustic detection scheme to detect a specific gas from a multicomponent gas mixture thereby avoiding cross-interference. Light from the infrared source is split into two paths. The chopper modulates the intensity for both paths. A filter volume in each path serves to filter out light of wavelengths not needed for the detection process; they can be filled with gases whose absorption spectra do not overlap with those of the species under scrutiny. M1 and M2 serve as measuring cell and reference cell respectively. With the help of the equalizer both light intensities become equal before entering the last cell. The last cell consists of two compartments with a membrane between them. Both compartments are filled with the gas under investigation so that all wavelength characteristics for this gas contribute to the signal. If the attenuation differs in M1 from that in M2 the membrane starts to oscillate with the frequency of the chopper. This oscillation (typically a few hertz) is detected capacitively.

detection cell unattenuated. When a specific compound, e.g. H_2O, causes spectral overlap, an extra cell can be placed in the light path filled with the interfering gas. This cell completely attenuates the wavelengths where this interfering molecule absorbs, including the spectral overlap regions. Thus, these wavelengths cannot contribute to the photoacoustic signal and a single component of a complex multicomponent gas mixture can be detected.

High spectral brightness renders CW (continuous wave) laser sources ideally suitable for photoacoustic trace gas detection. In contrast to direct absorption techniques, the photoacoustic signal is proportional to the laser power; from the Lambert–Beer law one finds for small absorptions (Equation 1)

$$P = P_0 e^{-\sigma N l} \longrightarrow (P_0 - P) \approx P_0 \sigma N l \qquad (1)$$

where P_0 and P are the laser power before and after the photoacoustic cell, respectively, σ is the absorption cross-section per molecule (in cm^2), N is the number of absorbing molecules per cubic centimeters and l the absorption path length (in cm). The absorbed energy $(P_0 - P)$ is converted into acoustic energy which is recorded by the microphone.

Saturation, due to nonlinear absorption of the laser power only occurs in focused high-power laser beams. The pumping rate to a higher rovibrational level is proportional to the laser light intensity; in the case of saturation it exceeds the collisional de-excitation rates.

Besides sensitivity, lasers achieve high selectivity. The spectral selectivity is only limited by the pressure broadened absorption profiles of the gases under investigation. The first practical lasers which were used to detect trace gases were CO_2 lasers.[11] These line tunable lasers cover the infrared 9–11 μm wavelength region with a laser line spacing of 0.5–2 cm^{-1}. Fingerprint absorption spectra can be achieved if we compare the laser line spacing to the pressure broadened absorption lines for the trace gas molecules (typically a few gigahertz at atmospheric pressures). Additionally, they are able to deliver high laser powers (1–100 W) from a relatively small gas discharge tube.

A new development is the application of the CO laser in its $\Delta v = 1$ (5.0–7.6 μm wavelength region) and $\Delta v = 2$ (2.5–3.8 μm) version. Although less powerful (typically 1 W) its performance can be improved by applying an intracavity set-up. CO lasers are line tunable with a line spacing between 0.5–1 cm^{-1}.

Other CW lasers in the visible and infrared have been applied to photoacoustic trace gas detection such as a spin flip Raman laser,[10] diode lasers[12,13] and dye lasers.[14] Although dye lasers and titanium sapphire do not cover the ideal wavelength region for trace gas detection they are very well suited for photoacoustic spectroscopy of weak absorption bands with their continuous tunability and a typical CW laser power of 1 W and they have proved their potential in molecular spectroscopy of highly vibrationally excited molecules.[15,16] However, for trace gas detection they are less applicable since the overtone molecular absorption cross-sections are weak, thereby raising the detection limits. For the same reason infrared diode lasers derived from telecommunication research (0.8 and 1.5 μm) are not very well suited.

Of periodically poled nonlinear crystals that have been developed, periodically poled lithium niobate (PPLN) is probably most well known.[17] Lithium niobate ($LiNbO_3$) can be used in combination with pulsed lasers to generate mid-infrared radiation (2–5 μm) by parametric oscillation. CW operation was limited to a few microwatts of laser power due to phase matching problems. Quasi-phase matching with periodically poled materials overcomes this problem resulting in laser powers up to a few watts in the infrared.[18]

The advantage of using pulsed lasers for photoacoustic detection is their wider infrared tunability and consequently better spectral overlap with interesting molecular gases. Examples can be given of the experiments performed with a pulsed CO_2 laser by Repond and Sigrist[19] and experiments with a pulsed optical parametric oscillator (OPO).[20] A disadvantage of pulsed lasers is their high peak powers (megawatt) in relation to their relatively low average energy (typically 1 W) which has to generate a relatively slow process as the gas phase photoacoustic

effect. Peak-to-peak fluctuation and nonlinear absorption disturb the reproducibility of the generated signal, thereby raising detection limits. Typical detection limits reported with these types of laser are in the parts per million range.

3.2 Photoacoustic Cells

To perform trace gas detection the ideal photoacoustic cell should amplify the generated sound originating from the molecular gas absorption meanwhile rejecting acoustic (and electric) noise and in-phase infrared absorption from other materials. Interfering gases should be distinguished by spectroscopic or physical methods (see section 3.3)

For gas phase measurements, mainly resonant cells are combined with modulated CW lasers and lock-in amplifiers; pulsed lasers are combined with piezoelectric detectors and boxcars. These selective amplifiers arise from the necessity to lower acoustic and electric noise levels thus improving the signal-to-noise ratio.

Other requirements for photoacoustic cells are a low gas consumption or a fast response; for this the active volume of the cell should be small so that no dilution can take place when the trace gas and its carrier flow through the acoustic cell.

If we consider a nonresonant, cylindrical cell, its performance can be expressed as its efficiency to convert absorbed photon energy into acoustic energy; this cell constant F (Pa cm W^{-1})[21,22] is given by Equation (2)

$$F_{\text{nonresonant}} = \frac{G(\gamma - 1)L}{wV} \tag{2}$$

where L and V are the length and the volume of the cell, respectively, γ is the specific heat constant, $w = 2\pi\nu$ the modulation frequency and G is a geometrical factor in the order of one. Within a nonresonant cell the gas absorption signal is independent of the cell length but inversely proportional to its diameter. However, photoacoustic signals are also generated by infrared window absorption. To reduce these signals inside the cell its length should be as long as possible to spread this locally generated sound over the total cell volume.

For a resonant cell, the above cell constant F must be amplified with the quality factor Q of the generated acoustic resonance, Equation (3)

$$F_{\text{resonant}} = QF_{\text{nonresonant}} \tag{3}$$

where Q is expressed by the ratio of the energy stored in the acoustical standing wave divided by the energy losses per cycle. This acoustical amplification process is limited by various dissipation processes which can be divided into surface and volume effects. Main surface losses are viscous and thermal losses at the resonator surface, microphone losses and acoustic wave scattering losses at obstacles in the cell. Volumetric losses are not as important as surface losses and are mainly due to free space viscous and thermal losses and $V-V$, $V-R$, $V-T$ relaxation losses of polyatomic gases.[23]

A cylindrical cavity can be a resonant cavity for sound waves. The resonance frequencies of such a cavity are given by Equation (4)

$$f_{mnp} = v_s \left(\left(\frac{\alpha_{mn}}{2R} \right)^2 + \left(\frac{p}{2L} \right)^2 \right)^{1/2} \tag{4}$$

where v_s is the sound velocity in the gas filling the cavity, R is the radius of the resonator, L is the length, $p = 0, 1, 2, 3 \ldots$ axial mode numbers and α_{mn} is a suitable solution of Bessel equations with $m =$ radial mode number and $n =$ azimuthal mode number (Figure 3).[24]

The cell constant F for all types of cylindrical resonant cells is proportional to $L^{1/2}/R$.[25] Due to their larger diameters resonances in the radial or azimuthal acoustic mode have high Q values and high resonance frequencies but low F values. A longitudinally excited resonator will have a low Q value but, due to its small diameter, a high F value.

In order to obtain an optimum signal-to-noise ratio, noise control and interfering signals have to be taken into account. Theoretically, the ultimately lowest acoustical noise results from random density fluctuations, i.e. Brownian motion, in the gas which is distributed over all frequencies in the sound spectrum. The total power of these density fluctuations is constant, but the frequency distribution is dependent upon local resonances and their Q values. Therefore, using a resonant cell the signal-to-noise ratio will not be improved by considering only these random thermal noise fluctuations.

However, these noise levels are far below other noise sources such as amplifier noise and acoustic disturbances from outside the cell. The power of the amplifier noise varies as $1/f$, where f is the modulation frequency of the light beam. Therefore, in contrast to Brownian noise, it is more advantageous to operate at a cell resonance to increase the generated acoustical signal above the $1/f$

Figure 3 Resonant acoustic modes of a cylindrical closed chamber; the fundamental longitudinal, azimuthal and radial modes.

noise. A prerequisite is that external acoustic disturbances are shielded from the microphone by a proper cell wall construction, material choice and proper design of inlet and outlet ports.

Noise fluctuations do not have a fixed phase relation with the modulation of the light intensity. Other disturbing factors limiting the sensitivity do have a fixed phase relation. Directly generated coherent acoustical background signals, caused by the modulation process (e.g. chopper, current modulation) can be suppressed in the same way as external acoustical disturbances.

Other, more serious interferences are coherent photoacoustic background signals which are caused by absorption of the light beam in the window material or light scattered or reflected off the resonator wall. They are generated at the same frequency and in-phase with the modulated light beam. In resonant cells, window absorption signals can be suppressed by using large buffer volumes and $\lambda/4$-tubes next to the windows.[25] These one-end-open tubes (Figure 4), placed near the window, act as a notch filter for the window signal at the resonance frequency. The influence of the scattered light on the photoacoustic background signal can be minimized by using, for the resonator wall, a highly reflective polished material, with a thermally well conducting material as substrate, e.g. in the case of the CO_2 laser, a polished gold coated copper tube.[26]

In the past special designs have been developed for longitudinally, azimuthally and radially resonant photoacoustic cells,[27–30] even without windows[31,32] to improve sensitivity.

In order to improve the selectivity the combination of the Stark effect or Zeeman effect with photoacoustic detection represents an interesting solution for specific molecules such as ammonia (NH_3)[33,34] and nitric oxide (NO).[35] The change in absorption at a specific laser frequency depends on the shift and splitting of the molecular absorption lines of the species under investigation. Although the method does not suffer from interference problems within multicomponent gas mixtures, there are some limitations. The detection is limited to molecules with a permanent electric or magnetic dipole moment; in addition, the shift or splitting of the lines should be observable within the pressure broadened Lorentzian profile at the overlap with the laser frequency. For ammonia at the 10R8 transition of the $^{12}CO_2$ laser these requirements are satisfied; Thöny and Sigrist[33] showed that the absorption cross-section changed by a factor of two at atmospheric pressure by applying an electric field of 16.7 kV cm^{-1}.

Another way to improve the sensitivity for a specific gas is by temperature change. By increasing the temperature the vapor pressure of, for example, an oil with low vapor pressure is increased thereby improving the sensitivity. An elegant cell has been designed by Jalink and Bicanic,[36] who combined a heatpipe and a photoacoustic cell thereby keeping the microphone and windows at room temperature. In addition, a Helmholtz resonant photoacoustic cell (Figure 5) has been developed by Kästle and Sigrist for quantitative temperature-dependent absorption measurements of fatty acid vapors.[37] Helmholtz resonances (w_H) can be constructed

Figure 4 Resonant photoacoustic cell. 1, resonator; 2, buffer volume (maximum diameter 40 mm, length 50 mm); 3, buffer ring to decrease buffer radius; 4, ZnSe Brewster window; 5, adjustable $\lambda/4$ notch filter to suppress window signal; 6, inlet gas flow; 7, $\lambda/2$ notch filter to suppress flow noise; 8, outlet gas flow; 9, Knowless microphone.

Figure 5 Photoacoustic cell applied for temperature-dependent investigations on fatty acids. The temperature of the water bath was varied between 278 and 350 K with a cold finger and two immersion heaters, while the temperature of the microphone was kept constant with a cooling/heating device. using a relatively large closed volume (V) connected to the outer world via a relatively long narrow duct (length L, cross-section S at a sound velocity c) Equation (5):[24]

$$w_{\mathrm{H}} = \overline{\frac{c^2 S}{LV}} \tag{5}$$

Amplification of sound waves can also be achieved with the thermoacoustic effect. The operating principle of such an amplifier connected to a photoacoustic resonator can be explained as follows. The gas inside the acoustical resonator is irradiated by an amplitude modulated laser beam. Trace gas absorption inside the resonator tube will produce a standing acoustical wave; this is the acoustic effect. The amplifier consists of a temperature gradient over a stack of thin sheets separated by a distance equal to two times the thermal boundary layer of the gas (Figure 6). If the gas is moving up and down over the temperature gradient inside the stack, heat energy is transferred to the gas and subsequently into the acoustic standing wave. With such a cell, Q values have been improved by a factor of 20–30.[38] By adjusting the amplifier just below the onset of self-oscillation, the acoustical wave in the resonator will put the amplifier in sustained oscillation, leading to a considerable enhancement of the photoacoustic signal. Noise, acoustic and photoacoustic background signals will also be enhanced. However, with careful design of the cell these levels can be suppressed thereby improving the signal-to-noise ratio.

3.3 Limitations, Selectivity, Interference, Detection Limits

Amplifying photoacoustic signals in resonant cells, reducing noise, using high laser powers, and so on are all used to gain an as high as possible sensitivity for molecular gas absorption. The sensitivity to trace a specific compound depends strongly on its spectroscopic properties. For example, closely spaced rotational absorption lines within a Q branch of a strong vibrational transition help to reach low detection limits of such a gas. One good example is the Q branch of the ν_7 band of C_2H_4 in the 10 μm region. The 10P14 CO_2 laser line is in exact resonance with this Q branch. This results in an extremely low detection limit for C_2H_4 of 6 parts per trillion (1 ppt = 1×10^{12}) in nitrogen. Some gases can be detected even better (e.g. SF_6) while others have higher limits due to less coincidence between available laser frequencies and molecular absorption features. In the future this problem may be overcome by powerful tunable infrared lasers such as the PPLN OPO[39] and quantum cascade lasers.[40] For detection limits see Table 1 and references therein.

Reactive gases such as ozone are very difficult to quantify in absolute concentrations, although ozone has a very strong absorption cross-section in the CO_2 laser wavelength region, resulting in sub-parts per billion detection limits. Ozone is highly reactive, thus interactions with tubing walls, sampling cuvettes, and the photoacoustic cell, cause rapidly decreasing ozone concentrations. This loss in concentration must be determined over the complete sampling system by calibrating the system with a specific ozone analyzer and checked for linearity over a large concentration range. For example, the breakdown of ozone over a 2-m sampling tube may be as high as 60%.[67] The degradation of ozone in a photoacoustic cell is determined to be 75% by inserting a second identical photoacoustic cell in the flow system. In spite of these limitations, successful studies have been performed to quantify atmospheric ozone concentrations.[68]

The first excited vibrational mode of N_2 has a long vibrational lifetime (≈1 ms at 1 atm (1 atm = 101.325 kPa) at $\nu_1 = 2200\,\mathrm{cm}^{-1}$). Using kilohertz modulation of the laser beam a phase shift may occur in the generated photoacoustic signal. A well known example is the kinetic cooling effect of CO_2 at CO_2 laser wavelengths (9–11 μm).[54,69,70] CO_2 has a hot-band absorption in this wavelength region and is excited to the ν_3 vibrational level which is almost resonant with the first vibrational level of N_2. Therefore, under atmospheric conditions the energy absorbed by CO_2 will only slowly be converted into a temperature and pressure increase of the gas.

N_2 is not unique. Another example is given in Figure 7 where CH_4 absorbs the CO laser radiation in

Figure 6 Expanded view of the thermoacoustic stack, dimensions are in millimeters. The tunable piston can slide in the upper part of the column which is cylindrically shaped (diameter 23 mm). The lower part (length 20 mm, square cross-section 23 × 23 mm) forms the connection to the stack. This part is heated by Inconel wire. The exploded view of the stack shows the stainless steel plates with the temperature gradient and copper plates to maintain the gradient; stainless steel spacers separate the plates. At the connection between thermoacoustic stack and the photoacoustic resonator, a water cooler removes the excess heat and keeps the lower end of the stack at constant temperature. [a] Unless indicated otherwise, detection limits are reported for single-component mixtures with N_2 at 1 atmosphere as buffer gas. Data are given in ppb (1 part per billion volume $= 1 \times 10^9$). In a number of references only absorption strengths are given: σ (in cm^2) or α (in $atm^{-1}cm^{-1}$), with $\alpha = N_{tot} \cdot \sigma$ ($N_{tot} = 2.5 \times 10^{19}$ molecules cm^{-3} at 1013 hPa and 20 °C). When the detection system has a sensitivity of typically $\alpha_{min} = 1 \times 10^{-8}$ the minimum detectable gas concentration can be calculated from $c_{min} = \alpha_{min}/(\sigma \cdot N_{tot})$.
[b] At $^{13}CO_2$ laser lines.
[c] Multicomponent study.

Figure 7 Vibrational energy transfer due to near-resonant energy levels and a slow V–T relexation process, in comparison with the modulation frequency (1010 Hz), may lead to an amplitude decrease and phase shift of the photoacoustic signal. This effect can, for instance, be observed when comparing mixtures of methane in nitrogen and in air, due to rapid vibrational energy transfer between methane and oxygen (see text for details).

the ν_4 vibrational mode centered around 1306.2 cm^{-1}. This is the lowest vibrational mode of the molecule; the collisional relaxation lifetime is therefore large compared with the lifetime of other molecules with a smaller energy gap between their lowest vibrational modes and the ground state. The adjacent ν_2 mode (1533.3 cm^{-1}) becomes thermally populated too (rate constant 13 μs^{-1} atm^{-1}).[71] Oxygen has a near resonant vibrational level (1554 cm^{-1}) and only 170 collisions are needed to transfer energy to the vibrational mode of O_2 (rate constant $\approx$28 μs^{-1} atm^{-1}).[72] Since this is a rather fast process most energy is deposited into O_2 and then relaxes slowly to the ground vibrational state; the average number of collisions required for relaxation to the ground state is 8.3×10^7 in pure O_2 (at standard temperature and pressure 5×10^9 collisions per second take place). The much larger number density of O_2 compared with CH_4 creates a buffer of vibrational energy leading to an effective transient cooling of the translational degrees of freedom. Due to our high modulation frequency (1010 Hz), we observed this transient cooling by O_2 as an amplitude decrease and a phase change relative to the signal caused by the same amount of CH_4 in N_2.

For specific molecules (such as NH_3, NO) spectroscopic interference can be avoided by combining the photoacoustic effect with the Stark or Zeeman effect; the selectivity is enhanced by intermodulating chopper and electric or magnetic fields. A more generally applicable method is to separate gases, either by gas chromatographic methods, selective trapping inside a cold trap,[26] or by a specific chemical reaction (e.g. CO_2 by KOH $\longrightarrow$ K_2CO_3 and water). In most cases, a small amount of the interfering compound remains present. To take this into account, a multicomponent analysis is necessary selecting a number of laser lines on which interfering species and the species of interest have both strong and weak absorptions.

For a multicomponent analysis of a gas mixture, the laser is subsequently tuned to L laser lines. For the analysis it is preferable to obtain an overdetermined system, $G < L$ with G being the number of gases; in this way, more information can be obtained from the gas mixture resulting in more accurate results.[60,73] For practical convenience the background signal generated by window absorption and/or resonator wall absorption is added as a fictive gas component. In the ideal case the measured spectrum is equal to the calculated spectrum. If the absorption coefficient $_{lg}$ of a gas g at laser line l is known, the total absorption at a laser line, α_l is given by Equation (6)

$$\alpha_l = \sum_{g=1}^{G} \Sigma_{lg} \cdot c_g \tag{6}$$

with c_g the concentration of component g. In matrix notation one writes Equation (7)

$$\vec{\alpha} = \vec{\vec{\Sigma}} \cdot \vec{c} \tag{7}$$

If no measurement errors are specified in the absorption coefficient matrix $\vec{\vec{\Sigma}}$ and the measured spectrum ($\tilde{\alpha_l}$), the gas concentration $\vec{c}$ can be calculated by[26] Equation (8)

$$\vec{c} = (\vec{\vec{\Psi}}^{\,t} \cdot \vec{\vec{\Psi}})^{-1} \cdot \vec{\vec{\Psi}}^{\,t} \cdot \vec{1} \tag{8}$$

where $\vec{\vec{\Psi}}^{\,t}$ is the transposed matrix of Ψ_{ij}, $\Psi_{ij} =$ $_{ij}/\alpha_i$ and $1_i = 1$

4 ENVIRONMENTAL APPLICATIONS

4.1 Stack Gas Emission

Several attempts have been made to measure stack gas emissions from power plants. Due to the high amount of nitrogen oxide (NO and NO_2) containing compounds in the emissions, they contribute significantly to photochemical smog formation and acidification of the soil. To reduce the total amount of NO_x in the stack gas, NH_3 is added in the exhaust gas towards the chimney. Using a voluminous catalyst, NO_x reduction within the stack gas takes place. In order to check the performance and to avoid an excess of ammonia injection, the ammonia concentration in the chimney is determined. Olafsson et al. have successfully applied a CO_2 laser-based photoacoustic detection system for in situ monitoring of ammonia concentrations.[74] Due to the difficult hostile environment halfway up the chimney (vibrations, temperature fluctuations, etc.), concessions have to be made as to the sensitivity of the apparatus. With a nonresonant photoacoustic cell at 125 °C, a detection limit of 1 ppm NH_3 was achieved in a multicomponent gas mixture containing 10–15% CO_2.

Gas detection using pulsed lasers in combination with photoacoustic spectroscopy in the UV (ultraviolet) and visible has been developed by Stenberg et al. to analyze gas concentrations in fluidized beds and other combustion environments.[75] The probe has been calibrated for typical combustion gases such as N_2O, NO, NO_2, NH_3, SO_2 and H_2S at temperatures between 20 and 910 °C.

Another example of the potential of the photoacoustic systems to control industrial processes is given by Sigrist[22] who was able to follow the ethanol and methanol emissions from a pharmaceutical production plant with a CO_2 laser-based set-up with a time resolution of 5 min. With this time resolution, strong concentration fluctuations were observed in the exhaust emission, whereas the gas chromatographic system which was used for comparison proved inadequate.

4.2 Car Exhaust Emissions

CO and CO_2 lasers were used to analyze the air polluting emissions from car exhausts. A thorough study was performed by Bernegger and Sigrist to unravel car exhaust mixtures quantifying CO_2, NO and 12 hydrocarbons (see Table 2).[76] To this end, absorption cross-sections of the individual species at each laser line were measured; certified trace gas mixtures in a buffer (mostly N_2) or other certified methods were used to quantify the absolute values. Once the absorption cross-sections are determined, care has to taken to avoid saturation effects (i.e. nonlinearity of the photoacoustic effect with the laser power[52]) and phase shift effects (see previous section). From the absorption cross-sections detection limits can be obtained. In the literature, extremely low detection limits are mentioned based on a signal-to-noise-ratio of one ($S/N = 1$, see Table 1), extrapolated from larger quantities of trace gases in a buffer gas. In reality the detection limits are higher due to multicomponent gas mixtures which induce cross-sensitivities in the absorption coefficients. This mathematical analysis of the photoacoustic spectra is based on the weighted least squares fit of the measured spectra with iteration steps. By choosing the best set of laser lines the error in the calculated concentrations can be reduced.[70,77]

Car exhaust gas mixtures have been investigated by collecting exhaust samples from different motorcycles, diesel and gasoline engines equipped with catalytic converter. The photoacoustic measurements were compared with conventional gas analytical methods. The engine exhaust stream was mixed with air and a fraction of the mixture was collected in a Tedlar sampling bag. Due to the strong water vapor absorption at the CO laser wavelengths and the high water vapor concentrations of 1–2% in the sampling bag, the gas was flowed over a dry-ice cold trap before analysis thereby reducing the water vapor concentration to 0.1%.[76]

4.3 Ambient Air Monitoring

Examples of laboratory photoacoustic studies on multicomponent studies can be found elsewhere.[22] Here we mention two examples of mobile systems which were developed and used in field campaigns. A complete laser photoacoustic system which fitted into two medium sized boxes (0.3 m^3 each) was developed by Rooth et al. to detect ammonia gradients above the heath in the Netherlands.[54] The potential danger of nitrification by NH_3 of such nutrition poor areas motivated the measuring campaign to follow the deposition/emission ratio of ammonia over the area. The system operated for several months, taking data for water vapor, CO_2 (every 40 min) and ammonia (every 6 min).

Another system was developed by Sigrist et al. Installing the whole set-up in a small trailer the stress on the equipment is less severe. Thanks to this approach the system has been operational for years and has been

applied in several field campaigns in urban and rural environments.[78] For example, multicomponent gas mixtures were analyzed during sunny days in the summer, using nine laser lines, for the concentration of H_2O, CO_2, NH_3, O_3 and C_2H_4 with a 5 min time resolution.

5 BIOLOGICAL AND MEDICAL APPLICATIONS

5.1 Postharvest Physiology

To delay the effects of aging and ripening, many harvested crops are stored under reduced oxygen concentrations thereby lowering the respiration rate and the rate at which metabolic processes take place. However, when the oxygen concentration falls below a certain limit, crops switch to fermentation, an alternative method to generate the energy needed to sustain their vital functions. This anaerobic metabolism, converts glucose, via several intermediate steps, into acetaldehyde which is then quickly reduced to ethanol. As accumulation of these products in the tissue may affect the quality of the crop, it is necessary to control the rate of fermentation during storage. The concentrations of the volatile in the headspace is an accurate quantitative indicator to assess the rate of fermentation.

Another gas of interest during crop storage is the plant hormone ethylene, which is mainly emitted during ripening of climacteric fruits, i.e. fruits which show a sudden rise in respiratory rate just prior to full ripening. Furthermore, carbon dioxide may be analyzed to assess both respiration and fermentation rates and ethane may be analyzed as the end product of lipid peroxidation causing breakdown of cell membranes.

The noninvasive nature of the photoacoustic trace detection technique renders it extremely suitable for applications in the field of postharvest physiology. Moreover, the high sensitivity combined with fast analysis allows study of an individual piece of fruit so that metabolic activity may be followed in real time. Here we give an overview of some recently performed experiments on single pieces of harvested crops. In general, the crop is placed in a glass container which is connected to the flow-through system leading the released metabolites to the photoacoustic cells. Storage conditions are simulated by supplying the sample with a premixed flow of oxygen and nitrogen (Figure 8); the storage temperature is controlled using a refrigerator.

Figure 8 Laser photoacoustic detection set-up. 1, 2 and 3, trace gas flows; 4, triple photoacoustic cell; 5, liquid nitrogen cooled CO laser; 6, grating to select the appropriate transition; 7, chopper; 8, catalyst to remove hydrocarbons from the flow toward the fruit; 9, KOH scrubber to remove CO_2; 10, switching valve for (an)aerobic conditions; 11, cuvettes, one containing a tomato, the other empty as reference; 12, switching valve to select cuvette; 13, cold trap to freeze out interfering gases selectively.

The ethylene emission of climacteric fruit shows a distinct rise during ripening, reaching a maximum when the sample is at its best; subsequent degradation of the product accompanies a decline in the ethylene release. To localize the ethylene release of different crops, De Vries et al. applied the extreme sensitivity of CO_2-laser based photothermal and photoacoustic detectors.[79] Huge differences in emission pathways were found ranging from more than 99% through the skin for banana, apple and citrus fruits, to around 85% through the pedicel "stem" for tomato and bell pepper. In addition, the amount of ethylene released varied from a few tenths to a few thousands of nanoliters per hour per fruit.

When stored crops are returned from controlled atmosphere (CA, low oxygen, high CO_2, low temperature) conditions to normal atmospheric conditions, a rapid peak in the acetaldehyde release occurs due to oxidation of the ethanol accumulated in the tissue. This process was followed in real time for red bell peppers by Zuckermann et al. using a CO laser-based photoacoustic detector.[80] Returning a pepper from anaerobic conditions to normal oxygen conditions (21%) caused a peak in the acetaldehyde release with a maximum of about four times the anaerobic level occurring within 25 min after the switch. The high velocity with which the process takes place caused the authors to conclude that the effect is mainly due to the peroxidative action of the enzyme catalase.[81] Further investigations[82] have shown that the acetaldehyde peak occurs even at much lower postanaerobic O_2 concentrations with roughly equal intensity, though not as fast (Figure 9).

During CA storage of apples it is common practice to apply low concentrations of carbon dioxide externally as it is known to inhibit respiration. As both respiration and fermentation produce carbon dioxide, it is difficult to predict a priori how the fine balance that exists between respiration and fermentation at low O_2 concentrations, will be affected. For pears, at oxygen levels around 1% a substantial rise in the acetaldehyde release could be observed upon addition of a few percent of CO_2. The crop is no longer able to retrieve its energy from respiration and is forced to generate additional energy through fermentation.

5.2 Plant Physiology

One of the major environmental factors influencing crop productivity is flooding. Tolerant species often possess

Figure 9 Emission of the precursor of ethanol in the fermentation process, acetaldehyde, is followed on-line while anaerobic conditions are imposed on a red bell pepper. Adding only 0.4% of O_2 results in a strong postanaerobic effect due to the oxidation of ethanol by transient free oxygen radicals in the tissue.

"escape" mechanisms such as fast underwater growth that minimizes the duration of total submergence.[83] However, at early vegetative stages, even in "deep-water" types of rice, such escape is precluded by a lack of sufficiently vigorous shoot elongation for resurfacing. Survival of submergence under these circumstances depends on intrinsic physiological and biochemical tolerance. Screening of cultivars is needed by plant breeders, agrotechnology and biotechnology to achieve sustainable improvements in productivity of rice farming in the rainfed lowland of southeast Asia.[84] Submergence is not an easily quantified stress compared with, for example, cold, heat, or pollution, since it cannot be assessed by one simple analysis. This is because it involves exclusion and entrapment of several key gases and interference with illumination. Normal rates of respiration and photosynthesis are affected; differences in submergence tolerance are also reflected in a different reaction to low oxygen concentrations. Precise measurements of fermentation rates can result in a powerful tool to shed some light on submergence stress. As mentioned in the previous chapter anaerobic fermentation in plant tissue can be studied by use of photoacoustic techniques, through detection of ethanol, acetaldehyde and CO_2 by means of a liquid nitrogen cooled CO laser. Experiments in the laboratory show that seed and seedlings of rice species with different degrees of tolerance toward submergence possess different fermentation rates under anaerobic conditions. Figure 10 shows that after a period of 5 h in which both species have similar ethanol production rates, the most tolerant species (FR13A) starts to slow down fermentation. After about 20 h the production rate for the less tolerant species (CT6241) is doubled with respect to the other; it probably runs out of storage material much faster than the resistant one.

Figure 10 Production rate of ethanol plotted against time for rice seeds during germination under anaerobic conditions. The flooding resistant species (FR13A)(■) does not ferment as much as the intolerant species (CT6241)(○) indicating that it preserves its energy for the postanaerobic period.

Besides fermentation, the availability of oxygen in the roots is of major concern for the plant. In case of partial or complete submergence, rice plants must rely on a well-developed system for gas transport through the plant. The real path of the gas (especially in the shoots) and how this changes with long periods of submergence is unknown. Photoacoustic trace gas detection can also be very useful in this case: a known amount of the tracer gas SF_6 (biologically inactive; atmospheric lifetime 3200 years) is injected into the nutrient solution around the roots and detected coming out of the tip of the leaves, while the rest of the plant is completely submerged in water. We use SF_6 as the tracer gas because the CO_2 laser photoacoustic system is particularly sensitive to this gas (down to parts per trillion level). Figure 11 represents a typical output from the tip of a leaf (enclosed in a cap) after the injection of 4.5 mL of H_2O saturated with SF_6. The plant is kept under water during the experiment.

A question we can readily answer with our system is what kind of gas transport is predominant in the shoots of a young rice seedling. It could be either through aerenchyma (i.e. intercellular spaces present in roots) or through the air layer that is wrapped around the hydrophobic surface of the leaves. This air layer is destroyed by dissolving a few drops of detergent in the water surrounding the plant; because the SF_6 signal dropped to zero immediately afterwards, we can exclude the presence of aerenchyma in the shoots of the seedling.

Figure 11 Depletion of the air layer around the submerged rice leaves by addition of detergent. The effect was monitored by SF_6 diffusion which was added into the root compartment (physically separated from the shoot compartment). SF_6 was collected from a small cap filled with air around the tip of a leaf. The air layer is completely restored by replacing the detergent with clean water. During the whole experiment the plant was kept completely submerged.

Another example of trace gas detection within plant physiology is the intriguing question of whether ethylene is a reaction to the growth of the pollen tube inside the pistil (i.e. a form of wounding) or if the pollen tube growth is a consequence of the hormone production by the flower (i.e. a real signal for the plant). It is known that a pollinated flower emits ethylene at the parts per billion level, with a characteristic double peak shaped curve.[85] To answer this question, incongruous pollination has been performed on tobacco flower (*Nicotiana tabacum*), i.e. by pollinating the flower with pollen from other species that show a certain degree of compatibility with the tobacco plant. For this we used pollen with a very low compatibility to the tobacco flower *Nicotiana repanda*; it enters the stigma and stops immediately thereafter. The production of ethylene, detected by photoacoustic spectroscopy, in these cases is very different, as shown in the Figure 12.

The first peak is always reproduced in both height and time and, comparing these results with microscopy work,[86] it corresponds to the entrance of the pollen tube in the stigma. The second peak has a more complicated shape which is never perfectly reproduced with incongruous pollination and which does not simply follow the growth of the pollen tube in the pistil. This might indicate that the second peak is a specific signal from the plant and not a simple wounding effect.

5.3 Microbiology

Biological systems cannot always use molecular nitrogen for their metabolic processes. To this end, dinitrogen

Figure 12 The in vivo production of ethylene during pollination of the *Nicotiana tabacum* flower with two types of pollen: *Nicotiana tabacum* and the incongruous pollen *Nicotiana repanda*. The latter enters the stigma and stops immediately thereafter, whereas the ''right'' pollen grows down the pistil into the ovary for fertilization. ■, *Nicotiana trigonofilla*; ○, *N. repanda*.

(N_2) must be reduced, i.e. the triple bond must be broken to convert the molecule into more appropriate compounds such as ammonium (NH_4^+), nitrate (NO_3^-) or amino acids. Only few organisms are capable of reducing dinitrogen; among them are the diazotrophic cyanobacteria.[87] The nitrogen fixation process is induced by the enzyme nitrogenase, which is very sensitive at low oxygen concentrations. However, like other organisms, cyanobacteria need energy which they derive from photosynthetically produced oxygen. In order to activate both photosynthesis and nitrogen fixation, these processes are separated either in time or in place.[88,89] *Nodularia spumigena* belong to the last category. They consist of large strings of cells formed mainly by vegetative cells in which photosynthesis takes place alternated every 10 to 20 cells by one heterocyst in which the nitrogen fixation takes place.[90]

The acetylene (C_2H_2) reduction method is commonly used to follow the process of nitrogen fixation.[91] As for N_2, the triple bond of acetylene is broken and reduced to ethylene (C_2H_4)[92] which can be detected very sensitively with laser photoacoustics.[52] In the past, gas chromatography utilizing flame ionization detection and photon ionization detection were applied to investigate the nitrogen fixation process.[91,93] Long incubation times, up to several hours, are necessary to reach gas concentrations observable for the equipment making dynamic measurements unfeasible.

Laser photoacoustic experiments have been performed to study the dynamic behavior of nitrogen fixation.[94] To avoid the buffering volume of the water, the algae *Nodularia spumigena* were put on filter paper and a gas mixture of O_2 and N_2 with different concentrations of acetylene was flushed over the sample. In this way the effect of parameters such as light intensity and temperature could be studied with a 20 s time resolution.

Utilizing the CO laser as radiation source instead of the CO_2 laser in the photoacoustic spectrometer, it is possible to detect other interesting gases. Methane and dimethyl sulfide emission in rice field paddies forms an important threat to the environment. Methane is, after CO_2, the second most efficient greenhouse gas whose biological production from the man-made rice cultures, needs further clarification.[95,96] Dimethyl sulfide is a climate-active natural marine emitter and responsible for sulfur transport into the atmosphere. The fact that both gases can be detected very efficiently by photoacoustic techniques, at the water surface as well as at various water depths, forms an important challenge for future activities at field sites.

5.4 Human Health, Noninvasive Breath Analysis

Since ancient times it has been known that the smell of exhaled air can be used as an indicator of several processes

taking place in the human body;[97,98] uncontrolled diabetes produces a sweet fruity odor, advanced liver diseases entail a musty fishy reek, failing kidneys bring about a urine-like smell and a lung abscess can be brought to light by its putrid stench. In the past, several attempts to use trace gas detection of exhaled air have been performed with variable success because of the nonsufficient detection limits of the detectors available. Gases produced in the body are transported to the lungs and are diluted (at rest, healthy persons exhale approximately $1000\,L\,h^{-1}$) before being exhaled. To measure them, it is necessary to enrich the air samples by adsorbing the gases on an agent and releasing the concentrated gas at a certain moment rendering the measurements less accurate and difficult to reproduce.[99]

Measurements on the effects of UV radiation on the human skin are presented to illustrate the possibilities of photoacoustic trace detection in this field. In these experiments lipid peroxidation of the skin is monitored.[100] UV radiation causes reactive oxygen species to be formed in the skin.[101] These radicals can damage the lipids in the cell membranes producing small hydrocarbons such as ethane, pentane and ethylene.[102] With the CO_2 laser set-up it is advantageous to study these latter molecules.[21,52]

A small amount of air is sampled from the exhaled air and cleaned from CO_2 (typically 5%), water vapor and other spectroscopically interfering gases like acetone and ethanol. The test persons are measured while resting under a solar bench. Under UV radiation a steady increase of the exhaled ethylene is observed with a 2 min time delay (Figure 13). The increase continues until the solarium is switched off after 15 min (the maximum exposure time advised). During the subsequent decrease of ethylene emission two decays can be distinguished; a fast and a slow decay. The first decay is caused by the washout of ethylene from the blood; the second decay results from ethylene stored in the body tissue. The dynamics of the system, i.e. transport of gases through the body, yields information for pharmakinetic research. In order to determine the locally induced damage, a specially designed cell was placed on the skin. Immediately after the start of the UV exposure a steady and constant production of ethylene in the skin was observed. Combining the two results, it is concluded that the slow increase in ethylene signal in the exhaled air is caused by the buffering effect of the human body.

Apart from the effect of UV radiation on the skin, other effects induced by lipid peroxidation can be studied: patients suffering from chronic obstructive pulmonary disease have increased cell membrane damage in the lungs; patients with pancreas problems cannot digest long-chain fatty acids, resulting in a lack of ethylene in the exhaled air after consumption of these fatty acids; patients suffering from cardiac insufficiency have increased ethylene levels in the exhaled air.

Figure 13 Ethylene emission from the human lungs induced by UV radiation from a solar bench. As a product of lipid peroxidation ethylene is found in low amounts in the exhaled air (a) and directly on the skin (b) utilizing a 5 cm diameter sample cell. The time during which the skin is irradiated (in total 15 min) is indicated by the black bar. Shielding the body from UV radiation using Lexan prevents generation of ethylene.

5.5 Entomology

Methane has been recognized as one of the principal greenhouse gases, second only to CO_2. Its estimated contribution to the enhanced greenhouse effect varies between 15–20% (Intergovernmental Panel on Climate Change, 1990) depending on the time window for which the calculation is made. Methane is not only a potent greenhouse gas, it is also chemically active in the atmosphere thus influencing concentrations of several important species, e.g. OH, O_3 and CO. Biogenic sources are responsible for the major part of the global methane flux (>70%).[103] Some arthropods (i.e. millipedes, cockroaches, termites and scarab beetles)

Figure 14 Methane release together with the CO_2 emission, during a complete respiration sequence of breathing (starting at 5.15 h and 6.08 h) and constriction (starting at 5.48 h and 6.32 h) for the cockroach species *Gromphadorhina portentosa*.

are believed to contribute up to 25% of the total budget.[104]

Gas chromatography allows measurement of the methane release of single animals only after incubation for several hours. Consequently these measurements cannot provide information about the dynamic character of the gas emission. Infrared absorption measurements featuring fast response time permitted observation of the dynamics of CO_2 emissions.

Besides CH_4 and CO_2 emissions from insects, water vapor release has been the subject of many studies. Information about water loss dynamics in insects is based upon theoretical modeling, sensitive weighing and relatively slow direct water vapor measurements.[105–108] With laser photoacoustic detection Bijnen et al. showed that cockroaches at rest show a regular breathing pattern that optimizes oxygen uptake and reduces water loss.[26] Respiration patterns of cockroaches and beetles have been recorded where microbiologically produced methane was found to be co-emitted with CO_2 and water vapor (Figure 14). This on-line observation is to be utilized in a study to establish conditions for hyperventilation of insects so that the minimum amount of insecticide will suffice to kill noxious insects which, for example, are known to transmit viral diseases.

6 COMPARISON WITH OTHER SPECTROSCOPIC METHODS IN TRACE GAS MONITORING

Fast and sensitive trace gas detection is not exclusively reserved for photoacoustics. In general, all spectroscopic techniques are able to monitor gas absorptions on a subsecond timescale. However, depending on the type of application not all techniques possess a high sensitivity.

Air pollution can be very well studied with long-path light absorption techniques rendering low detection limits; the sensitivity of the method relies strongly on the path length. A broadband light source (often UV) is directed towards a receiver over an open path in the atmosphere.[22] For stratospheric studies the sun has

also been used as a light source applying a $0.01\,cm^{-1}$ resolution Fourier transform spectrometer on board the space shuttle as part of the Spacelab 3 mission.[109] Laser-based long-path absorption techniques are used either with multipass arrangements, LIDAR (light detection and ranging) or the related DIAL (differential absorption lidar) methods.[22] In contrast to CW operation, using pulsed lasers has the advantage that the backscattered light gives spatial information about the atmospheric absorption pattern.[110]

All methods described above derive their sensitivity from long-path absorption thereby integrating over hundreds of meters. Laser-based photoacoustic detection has the advantage of tracing gases locally and can therefore also be used in laboratory studies. Other laser-based techniques which can also achieve a high sensitivity within a small volume of gas are intracavity laser absorption spectroscopy, which relies on very long effective absorption length within a high optical Q factor laser cavity;[111] cavity ring down spectroscopy combines very accurate decay time measurements of light pulses and a high Q optical cavity resulting in long effective absorption lengths.[112] In comparison with these techniques laser photoacoustics has the advantage that it is background free: it does not rely on a decrease of the transmitted light but on an increase from the zero baseline, i.e. on a collisional release of energy after absorption.

Other background-free and therefore strongly competitive techniques are laser-induced fluorescence (LIF) and multiphoton ionization (MPI). These techniques are both extremely sensitive due to the high collection efficiency of photomultipliers and ion counters; both can be applied locally within a small gas volume. LIF and laser photoacoustics are complementary in energy release. The advantage of LIF is that it can also detect free radicals (e.g. OH) with relatively low laser powers. MPI can be very selective and sensitive for molecules with a higher mass. An elegant example is the detection of OH with LIF in the upper atmospheric layers with an aircraft, avoiding spectroscopic cross interferences from other molecules, laser-induced generation of OH, depletion of OH during sampling, etc.[113] A restriction of LIF is the lifetime of the excited levels. As stated in the introduction, the competition between collisional relaxation and radiative decay restricts LIF mainly to the visible and the UV part of the electromagnetic spectrum.

ACKNOWLEDGMENTS

The authors wish to thank D.H. Parker and J. Reuss for their helpful discussions and continuous support. We are also grateful to H. Zuckermann (Open University of Israel), H.S.M. de Vries, J. Oosterhaven and R.H. Veltman (ATO-DLO) for their collaborations in postharvest research; M.B. Jackson (University of Bristol, UK) for his indispensable contribution in the rice plant research; C. Mariani (University of Nijmegen), D. de Martinis (ENEA, Italy) for their pollination research; M. Staal, L. Stal (NIOO) for their contributions in the field of microbiology; R. Berkelmans, K. Kuiper, P. Hollander (Free University, Amsterdam), P. Scheepers, R. Dekhuijzen (University of Nijmegen) for their help in breath analysis; and P. Kestler (University of Osnabrück, Germany) and J. Hackstein (University of Nijmegen) for their collaborations on entomological applications. Furthermore we thank F. Bijnen, S. Persijn, T. Groot, E. Santosa for their experimental support and C. Sikkens, C. Timmer, H. Schoutissen and L. Gerritsen for technical assistance. Finally we would like to thank the Dutch Technology Foundation (contracts no: NNS44.3404, NNS.4596 and NNS55.3921), the Dutch Royal Academy of Science (contract 95BTM04) and the European Union (contracts no: BRFSCI-CT91-0739, ERB3514-PL95-0708, PL95-0468 and ERB4062-PL970089) for their financial support.

ABBREVIATIONS AND ACRONYMS

CA	Controlled Atmosphere
CW	Continuous Wave

Recent progress in light detection and ranging (LIDAR) and differential absorption light detection and ranging (DIAL) technology has allowed three-dimensional (3-D) mappings of concentrations of air pollutants to be obtained at the highest sensitivity (parts per billion) and over large distances (several kilometers). It is now possible to monitor on-line spatial distributions of nitrogen oxides, sulfur dioxide, ozone, benzene, toluene, and aerosols. With the advent of new tunable *all-solid-state laser systems, such as vibronic lasers and optical parametric oscillators (OPOs), LIDAR systems have furthermore reached the highest industrial standards in terms of reliability and ease of operation. An overview of results and capabilities of ''all-solid-state'' LIDAR/DIAL systems is presented. The examples of application include detailed urban studies performed in large cities (e.g. Berlin, Leipzig, Lyon, Stuttgart, Geneva, Athens, Seville), with special attention to the first direct access to smog formation processes and tropospheric ozone generation. Industrial applications are also numerous, such as site monitoring, identification of diffuse emissions, and evaluation of the impact of new emitters through plume dispersion studies. The use of LIDAR systems to validate numerical models is also discussed. The last section is dedicated to the calibration of the systems, intercomparison with standard analyzers, and legal aspects in terms of certification and new standards.*

1 INTRODUCTION

Air pollution is an extremely dynamic phenomenon, which makes its understanding and therefore its control difficult. This dynamic behavior appears in physical terms in the diffusion and transport of emitted pollutants and chemically through the many reactions which take place in the atmosphere. It is therefore of outstanding importance to be able to correlate emission and immission, and characterize the impact of different kinds of sources of pollution (industries, vehicles, domestic heaters) on the environment. Currently existing devices, however, although very sensitive, only provide spot measurements at the ground level. 3-D information, reflecting the dynamic character of pollution, has been for a long time sorely lacking.

These considerations have induced the development of the LIDAR technique, and in particular DIAL [also called differential absorption and scattering (DAS)]. These devices indeed allow selective measurements of pollutant concentrations over several kilometers, range-resolved like radio detection and ranging (RADAR), and in an interactive manner (i.e. without the usual need for samples). It becomes then possible to obtain ''3-D maps'' of concentrations, which show the propagation, spread, and chemical evolution of emitted pollution.

The DIAL technique was demonstrated for the first time in 1966 by Schotland,[1] who evaluated vertical profiles of water vapor contained in the atmosphere. The first mapping experiments were performed in 1974 by Rothe et al.[2] In the 1980s, the performances of the systems were widely extended by several research groups, essentially in Sweden,[3–7] England,[8,9] Germany,[10,11] France,[12–14] and the United States.[15–17]

However, LIDAR systems remained in the laboratory until very recently. The breakthrough to industrialization and standard use by the Environmental Protection Agencies (EPAs) has been allowed by different conjugated progress. First, the capabilities of today's DIAL systems almost perfectly match the needs and requirements of air enforcement regulations. In particular, LIDAR provides 3-D maps of concentrations of nitrogen oxides, sulfur dioxide, ozone, toluene, and benzene at the highest sensitivity (parts per billion range), over large distances, and

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

this at much higher resolution and lower cost than standard networks. It is also, moreover, able to monitor the time evolution of pollutant concentration distributions, at high temporal resolution (some minutes) or in longer time frames.

Optical techniques are moreover often recognized as delivering more representative data than spot measurements: an integrated value over a defined optical path (ranging from few meters to several hundred meters) always contains more information than precise spot data at a wrong location! These arguments brought standardization commissions to introduce optical techniques into legislation. Pioneering work has been performed in this respect by the German commission Verein Deutscher Ingenieure (VDI)/Deutsche Institut für Normung (DIN).[18,19]

The most recent and decisive progress is a technological step forward, which makes the new DIAL systems very reliable devices, reaching the highest industrial standards. The advent of new *tunable* all-solid-state laser systems, such as vibronic lasers[20–22] or laser-pumped OPOs[23,24] has opened up a new era in the domain of user-friendly and fully automatic DIAL operation.

''All-solid-state'' DIAL systems, based on flashlamp-pumped Ti : sapphire lasers, have recently been very successful.[21,25,26] The development of the laser used was fully dedicated to LIDAR applications, in order to reach the specific requirements such as high energy, dual-wavelength operation, extreme reliability, and user-friendliness. The wavelength range accessible by the laser and its extension by non-linear optical devices make it an ideal tool for both DIAL and meteorological applications.

DIAL instruments can be classified in two different categories, depending on the application: stationary and mobile. The stationary systems, such as those installed in Berlin and Leipzig,[20] are dedicated to routine 3-D mappings over the city, whereas mobile units are mainly used for campaigns. Numerous campaigns have been performed in large cities such as Zürich,[27] Stuttgart, Lyons, Geneva,[28] Berlin,[29] Athens,[30,31] Seville,[32,33] and Mexico.

This article discusses the advantages offered by DIAL/LIDAR instruments in analyzing gaseous and particulate pollutants, examples of application, and norming activities.

2 THE DIFFERENTIAL ABSORPTION LIGHT DETECTION AND RANGING TECHNIQUE

When a laser beam is sent into the atmosphere, it is scattered in every direction by particles and molecules present in the air. This scattering is essentially caused by Rayleigh scattering on nitrogen and oxygen molecules and Mie scattering on aerosols (dusts, water droplets, etc.). In a LIDAR arrangement, the backscattered light is collected by a telescope, placed close to the laser emitter (see Figure 1). The signal is focused on to a photodetector through a spectral filter, adapted to the laser wavelength. Since a pulsed laser is used, the intensity of the backscattered light can be recorded as a function of time, which provides spatial resolution. The received signal reflects the aerosol and molecular concentrations as a function of distance, similar to an ''optical RADAR''. More precisely, the received number of photons from a distance R at a wavelength λ is given by Equation (1) (assuming that each photon is only scattered once):[34]

Figure 1 Principles of the LIDAR/DIAL technique.

$$M(R,\lambda) = M_0(\lambda)\,\frac{A_0}{R^2}\,\beta(R,\lambda)\,\Delta R\,\xi(R,\lambda) \times \exp\left[-2\int_0^R \alpha(R',\lambda)\,\mathrm{d}R'\right] \quad (1)$$

where $M_0(\lambda)$ is the number of photons emitted by the laser, A_0 the area of the receiver telescope, ΔR the spatial resolution of the system, essentially limited by the laser pulse duration and the dwell time of the acquisition electronics, $\xi(R,\lambda)$ the detection efficiency, $\beta(R,\lambda)$ the volume backscattering coefficient, and $\alpha(R',\lambda)$ the total atmospheric extinction coefficient.

The detection efficiency $\xi(R,\lambda)$ takes into account every geometrical and optical factor of the receiver arrangement. $\xi(R,\lambda)$ can be separated into two different parameters, one dedicated to the spectral characteristics $\xi(\lambda)$ of the detection channels (filters, monochromator, etc.) and of the sending and receiving optics, and the other, $\xi(R)$, to geometrical properties such as the overlap between the field illuminated by the laser and the telescope field of view. The latter parameter is often used to somewhat compress the large dynamic range of the signal.[35,36]

The signal dependence on the aerosol concentration, which allows their detection, is included in two scattering parameters: the volume backscattering coefficient β and the extinction α. However, the exponential factor $\exp[-2 \int \alpha(R', \lambda)\, dR']$ represents the total atmospheric attenuation of the laser beam, via the Beer–Lambert law. The extinction is caused by two different processes: the Rayleigh–Mie scattering α_{RM} and the specific molecular absorption α_A of the different species present in the atmosphere. The extinction coefficient α_{RM}, like β, is an average value of the size distribution, shape, and composition (refractive index) of the aerosols. In order to solve Equation (1), a standard method is to use a fitted value of the α_{RM}/β ratio.[37,38] This provides backscatter ratios as a function of distance, which *qualitatively* represent the spatial distribution of the atmospheric particle density.

The molecular absorption α_A allows a specific detection of a particular gaseous pollutant, using the DIAL technique. This technique is based on the use of a pair of wavelengths close to each other, with a large absorption coefficient difference (called λ_{on} and λ_{off}, for on-resonance and off-resonance wavelength, respectively).

Let us now assume that such a pair of wavelengths (λ_{on}, λ_{off}), chosen for the detection of a pollutant B, is sent into the atmosphere (Figure 1). It is important that λ_{on} and λ_{off} lie close enough to exhibit the same scattering properties. So, the first plume A in Figure 1 (which does not contain the detected species B) causes an increase of the backscattered signal, because the concentration of aerosols is larger than in the clear atmosphere, but the same amount for both pulses. Conversely, the second plume, which contains a certain quantity of the pollutant, absorbs the backscattered signal at the λ_{on} wavelength much more strongly than at the λ_{off} wavelength. From this difference, using the Beer–Lambert law, we obtain the specific concentration of the considered pollutant as a function of distance. More precisely, if we take the ratio of the two LIDAR returns (each represented by Equation 1), and then the derivative of its logarithm, we obtain Equation (2):

$$N_A(R) = \frac{1}{2[\sigma(\lambda_{on}) - \sigma(\lambda_{off})]} \frac{d}{dR} \ln \frac{M(R, \lambda_{off})}{M(R, \lambda_{on})} \qquad (2)$$

where $N_A(R)$ is the pollutant number density and $\sigma(\lambda)$ the absorption cross-section at the wavelength λ. Note that to obtain Equation (2), the detection efficiency $\xi(R, \lambda)$ must be the same for both laser beams, so that a perfect geometric alignment is necessary.[39] As mentioned before, both wavelengths must be taken close enough so that the backscattering and extinction coefficients are identical, i.e. $\beta(\lambda_{on}) = \beta(\lambda_{off})$ and $\alpha_{RM}(\lambda_{on}) = \alpha_{RM}(\lambda_{off})$.

The pollutant concentration is then measured range resolved. By scanning the measurement direction in azimuth or elevation, two-dimensional (2-D) or 3-D mappings are obtained, like a molecule-specific RADAR.

3 DIFFERENTIAL ABSORPTION LIGHT DETECTION AND RANGING SYSTEMS

In the 1980s, ultraviolet differential absorption light detection and ranging (UVDIAL) systems were mainly based on dye lasers, pumped by frequency doubled or tripled Nd : Yag or excimer lasers. The dye laser output was then frequency doubled to reach the 225–400 nm region,[63] where major pollutants (nitrogen oxides, sulfur dioxide, ozone, etc.) exhibit strong absorption features. The complexity and user unfriendliness of these laser systems definitely prevented the widespread of LIDAR systems at this time.

The advent of high-energy, tunable, all-solid-state lasers in the early 1990s completely changed this situation. DIAL systems were finally considered as reliable ''black boxes'', which could be widely used for air pollution monitoring applications. This also induced industrial developments of DIAL systems. The first ''all-solid-state'' UVDIAL system commercially available, based on a flashlamp-pumped Ti : sapphire laser, was for example presented in 1993.[41]

Since then, Ti : sapphire-based UVDIAL systems have been very successful. A typical example of such an instrument, manufactured by Elight Laser Systems, is presented below.

The laser is a flashlamp-pumped Ti : sapphire laser in an oscillator/amplifier configuration. A patented oscillator,[42] based on a dual prismatic dispersion arrangement, provides both reference and probe wavelengths (λ_{on} and λ_{off}), either simultaneously or alternately. The switching is performed by a rotating-face parallel prism allowing collinearity between both laser beams of better than 100 µrad. The use of a *single laser* drastically reduces maintenance.

Mode quality and frequency stability are assured by a graded reflectivity (super-Gaussian, 50% maximum) output coupler. With a Pockels cell as Q-switch, this laser system delivers 250 mJ in 20 ns pulses with a bandwidth of 0.5 cm^{-1} over the whole tuning range (720–900 nm).

The high peak power allows efficient nonlinear optical frequency conversion [second harmonic generation (SHG) ~20%, third harmonic generation (THG) ~7% of the fundamental] to reach the ultraviolet (UV) absorption bands of the detected pollutants. The laser beam is expanded 10× to meet eye safety requirements (according to VDI/DIN 0837).

Figure 2 ''All-solid-state'' mobile LIDAR/DIAL system.

Note that for the eye safety reasons mentioned above, some weaker bands of pollutants have to be chosen instead of stronger ones, which lie above 400 nm and lower than 1400 nm. The laser beam is sent into the atmosphere by a dual scanning periscope in composite material which also directs the backscattered light back to the 400 mm/f3 parabolic mirror (Figure 2). This telescope focuses the light on to an iris to limit the field of view to about 0.5 mrad. The signal is detected by a photomultiplier, through a motorized filter wheel, in order to select automatically the proper spectral filter. The signal is digitized by a 12 bit, 40 MHz system, allowing a spatial resolution of 3.75 m in this case (for some emission measurements faster analog-to-digital converters are used). The data are handled by a PC microcomputer which controls every parameter: wavelength setting and calibration, receiver parameters [photomultiplier tube (PMT) high voltage, gain, spectral filter used], and the periscope steering. The software is Windows-based, and includes a sophisticated inversion algorithm optimising the signal-to-noise ratio (S/N), and modules for automatic operation, on-line evaluation of the data, and high-level graphic representation.

The described instrument is moreover of very compact design (110 × 100 × 120 cm), which allows its installation in a small van (e.g. a Mercedes MB 100). It is able to perform 3-D mappings of NO, NO_2, SO_2, O_3, benzene, and toluene at high sensitivity (a few parts per billion) and over large distances (several kilometers). Typical specifications are listed in Table 1.

An additional extension of the accessible wavelength range, in particular in view of hydrocarbon detection, is made by an OPO in a ''no-tracking'' configuration. The decisive advantage of pumping with a tunable laser such as Ti : sapphire is that no geometrical alignment of the OPO is necessary.[23,43] The device can even be monolithic with mirror coatings directly applied on the nonlinear crystal facets. With such a device, infrared (IR) radiation from 1 to 4 μm is generated with an efficiency of up to 10% just by tuning the pump wavelength from 730 to 860 nm.[43]

Recently, a new aspect was brought out by Douard et al.[44] concerning multi-DIALs. The idea is to send a broad-band laser (like a free-running OPO) in the atmosphere and to analyze spectrally the backscattered light by an optical multichannel analyzer (OMA) or a Fourier-transform infrared (FTIR) interferometer. This technique was demonstrated for the first time in 1995.[44] The decisive advantage of the method is the capability of detecting several species by DIAL at the same time. A very attractive application is thus the detection of volatile organic compounds (VOCs) in the mid-IR region (3.3–3.5 μm).

It should be noted at this point that taking into account the different sources of noise and error, the sensitivity is actually a value in parts per million times meters, because of the Beer–Lambert law: for a given S/N, the larger the range of integration, the lower the possible detected concentration. For example, if the detection limit is 1 ppm m, the lowest detectable level is 1 ppm for a range resolution ΔR of 1 m (emission conditions), but 5 ppb for a range resolution of 200 m (immission conditions).

The maximum distance of measurement is typically 3 km for standard meteorological conditions. The sensitivity and the absorption path can be increased in a large extent by using topographic targets down to about 500 ppt for a 10 km pathlength.[45] Nevertheless, the spatial resolution is then lost in one direction, and only average 2-D mappings are obtained.

Table 1 Specifications of a Ti : sapphire-based UVDIAL system[41]

Pollutant	λ_{on} (nm)	λ_{off} (nm)	K (cm^{-1} atm^{-1})	Energy (mJ)	Sensitivity (ppb)	Range (km)
SO_2	286.55	285.7	10.2	5	8	3
O_3	283.0	287.0	27.4	5	4	3
NO	226.80	226.83	105	1	2	1
NO_2	398.29	397.5	4.5	25	15	4
Toluene	266.9	266.1	29.5	7	7	3
Benzene	258.9	257.9	38.7	7	5	3

4 EXAMPLES OF THREE-DIMENSIONAL MAPPING OF GASEOUS POLLUTANTS

We present in this section several examples of DIAL measurements of gaseous pollutants. The first part is dedicated to the study of physical atmospheric dynamics, and in particular to transport processes and spread of primary pollutants in different topographic and meteorological conditions.

The first application consists in emission measurements in industrial environments. Figure 3 shows a typical example of a DIAL concentration profile. The detected pollutant is SO_2. The measurement was performed directly through the chimney plume of a power plant. This example shows the ultimate spatial resolution of the system,[43] of about 2 m, which allows the observation of the structure of the plume. The two concentration maxima are, indeed, due to the use of two separate burners in the combustion chamber. The measured SO_2 values are, furthermore, in good agreement (within $\pm 10\%$) with the standard spot measurements, performed by the company inside the chimney.[46] Moreover, remote sensing allows the plume concentration to be followed as a function of distance, and thus to characterize the dilution and its expected impact (see section 6).

Scanning the measurement field in azimuth or elevation yield the unique access to tridimensional maps of concentration. Figure 4 represents such a map of the NO_2 concentration emitted by a chemical factory. The high spatial resolution allows here to observe long-living macroscale turbulence inside the plume and gives a real picture of the plume dispersion and transport. A simultaneous air speed measurement leads to the emitted mass concentration flux.[26,47] This speed is often determined by correlation of video pictures of the aerosols

Figure 3 Remote SO_2 concentration measurement by LIDAR at the top of a chimney of a power plant.[46]

Figure 4 3-D mapping of NO_2 emitted by a chemical factory.

contained in the plume or by correlation of the LIDAR returns themselves.[6,48]

Note, however, that such 3-D mappings require relatively stable weather conditions, since the total measurement time in this case is 15 min. The atmospheric fluctuations in plume measurements by DIAL must therefore be carefully considered, so that the measurement time always fits the timescale of the monitored process.[11,49] Microscale, fast fluctuations may also induce errors in DIAL measurements of emitters, since the λ_{on} and λ_{off} wavelengths are usually sent alternately since they have to remain close to each other and thus cannot be spectrally separated in the detection chain. The switching time between the two wavelengths is critical because microscale fluctuations of concentration may be fast enough to induce errors.[50,51] In the UV and for DIAL measurements other than plume tracking, it has been demonstrated that atmospheric fluctuations do not induce significant errors in the results[49] and that shot noise is the major limitation.

If the characterization of identified emitters such as plumes is highly relevant in terms of impact on the environment, the use of DIAL systems in industrial environments is even more interesting for diffuse or unclassified emitters. An example of a toluene profile obtained over a petrochemical plant in Cubatao (Brazil) is presented in Figure 5. It clearly shows the diffuse emission of a storage tank of gasoline: the floating roof periodically exhausts some toluene bursts, which then move to higher altitudes. These emissions are usually very difficult to quantify or even to detect with standard techniques, although they may amount to as much as the classified emitters in some cases.[47]

The most important source of diffuse and ''moving'' emission of atmospheric pollution is obviously road

Figure 5 Diffuse toluene emission from a storage tank.[41]

Figure 6 NO mapping over Lyons.[28]

traffic, so extensive studies have been performed in urban conditions. In particular, DIAL measurement campaigns in large European cities have provided very important information about the influence of urban topography.[28] Figure 6 presents a map of the NO concentration over the city of Lyons. Since Lyons is a relatively flat, well-ventilated city, the traffic-related pollution is efficiently spread, and the highest values (102 ppb) are recorded for narrow streets in the old part of the city, where a few vehicles are moving slowly, and not over the main avenues. Vertical gradients have been determined in these narrow street canyons: a dilution factor of 5–6 was usually recorded between the ground level and the canopy, attesting to the poor ventilation.

The topography of Stuttgart is opposite to that of Lyon, with a shape close to a ''Mexican'' hat, where the vertical air mass exchanges are strongly hindered. As a result, inversion layers, where air pollution is trapped, appear frequently, as shown in Figure 7. NO concentrations as high as 150 ppb have been recorded by DIAL inside this layer. Owing to the valley shape of the region, this layer reaches the outer residential quarters of Stuttgart more dramatically than the city center, although the primary NO pollutant is mainly emitted in the city center.

In addition to emission intensity and topography, meteorology also plays a crucial role in the distribution of air pollutants and in the formation of smog situations.

Figure 7 Inversion layer over Stuttgart.[28]

This is demonstrated in the case of Geneva in winter 1989. Figure 8(a) exhibits a typical smog situation, where high NO concentrations are recorded everywhere, without steep gradients, although NO is a primary, traffic-related pollutant. The concentrations increase almost without limit because of the lack of air motion. Two days later, a north wind destroyed this local equilibrium and blew the air masses out from the Geneva valley. This led to a return to a normal situation (Figure 8b), with steep gradients and lower concentrations. The Mont Blanc bridge, usually strongly subject to traffic jams, does not suffer too much, again because of good ventilation from Lake Geneva and the River Rhone. However it should be noted that the high value of 92 ppb remained over the English Garden (''Jardin Anglais''). It was found that this local maximum was due to the air conditioning system exhaust of the large underground car parking located under the Garden.

This example emphasizes the difficulty of obtaining a realistic picture of the air quality in a city with standard networks, and especially the difficulty of finding representative locations for spot analyzers. DIAL measurements provide very useful information in this respect.

An especially attractive application of DIAL is in tracing pollution in trans-border importation/exportation situations. An example of a study of this kind was performed during an intensive LIDAR campaign in Berlin in January 1989, in order to quantify the transport processes between East and West Berlin. At this time, the Berlin Wall still existed, and the West German pollution regulations were applied to West Berlin, although no sanitation actions could be taken in East Berlin. Even the concentration values of pollutants at ground level in East Berlin were not available. A typical result of this campaign is shown in Figure 9.

The directions in which the vertical profiles were recorded were chosen in the south-east (SE) wind direction and at 90° from it. In the SE direction (East

Figure 8 NO mappings over Geneva (a) during and (b) after a smog situation.[28]

Berlin) the SO_2 values reach 140 ppb at ground level and then smoothly decrease with altitude until a set of inversion layers between 400 and 600 m. The emitted concentrations at ground level are mainly due to coal burners. In the north-west (NW) direction (West Berlin), ground level values are much lower, while at 600 m a maximum is found, demonstrating pollution transport processes. At 90° south-west (SW), the maximum is located at lower altitude, confirming the interpretation of importation from SE to NW.

A more direct importation process has been recorded, related to the power plant ''Mitte'' located in the center of East Berlin. For this, the DIAL system was placed

Figure 10 Importation in former West Berlin from a power plant located in former East Berlin.

Figure 9 Vertical distributions of SO_2 over Berlin in January 1989.

close to the former Berlin Wall, about 1 km from the emitter (Figure 10). The SO_2 plume was followed for over 2 km, delivering very precise information. Besides the mass concentration fluxes determined from DIAL measurements just at the chimney output, it could be clearly observed that, again, two burners were used, and that their related plumes did not mix with the distance. It was also shown that more than 500 ppb of SO_2 were ''imported'' over West Berlin from this emitter at that time.

Routine monitoring is also a standard application of LIDARs. A stationary DIAL system has been implemented in the center of Leipzig since 1992. Figure 11(a) shows a typical map of SO_2 over the city. Such maps can be recorded hourly and give average information about air quality. However, if a higher concentration is observed in some direction, a ''zoom'' can be performed at higher spatial resolution (a few meters) and in three dimensions. The example of a power plant located 1.5 km from the station is shown in Figure 11(b). This allows us to determine the plume dimensions and dilution over more than 1 km, and then obtain a more accurate estimate of the effects of this particular emitter in the former low-resolution map, i.e. a direct correlation between emission and immission.

After these examples of accessing physical dynamics with DIAL, let us now focus on chemical and photochemical processes. As an example, we present here the results of a measurement campaign on ozone in Athens in summer 1994. Ozone is one of the most important pollutants responsible for the summer ''smog'' recorded in large urban areas. Its formation is particularly due to the emission of road traffic (nitrogen oxides, VOCs) combined with sunny periods. Photolysis is the dominant loss process for NO_2 in the troposphere and the major source of tropospheric O_3 (Equations 3–5):

$$NO_2 + h\nu \longrightarrow NO + O(^3P) \quad (3)$$

$$O(^3P) + O_2 + M \longrightarrow O_3 + M \quad (M = \text{air}) \quad (4)$$

$$O_3 + NO \longrightarrow O_2 + NO_2 \quad (5)$$

In the absence of other processes that convert NO to NO_2 and assuming steady-state conditions, one obtains the well-known Leighton relationship [Equation 6]:[53]

$$[O_3] = \frac{j_3[NO_2]}{k_5[NO]} \quad (6)$$

The ozone production depends in this very simple case on the solar irradiation-dependent rate j_3 and the rate constant of Equation (5), k_5. However, it has been shown

Figure 11 Routine measurements over Leipzig and 3-D "zooming" on to an emitter.[38]

that VOCs also play a key role in ozone formation, and in particular enhance the NO to NO_2 conversion and thus favor ozone production. A comprehensive description of the many reactions involving NO_x and VOCs can be found in a reference book published by the National Research Council.[54]

Ozone production is usually plotted in the form of isopleths as a function of the VOC and NO_x concentrations. The isopleths have roughly the shape of a hyperbola, and the diagram characteristically exhibits a diagonal ridge from lower to higher concentrations. This ridge is more or less a straight line of a given VOC/NO_x ratio. Depending on the value of the VOC/NO_x ratio encountered in the atmosphere, the ozone production can thus be either NO_x-limited (high VOC/NO_x ratios) or VOC-limited (low VOC/NO_x ratios). The location of the ozone maxima will thus be determined by the VOC/NO_x ratio and not by the isolated NO_x or VOC concentrations.

Athens is a very interesting example of ozone smog formation. Meteorological and photochemical dynamics are combined to form ozone in high concentrations. Athens is located in a basin, and thus subject to a back and forth motion of air masses from the sea to the ground. Hence cold wind flows from ground to sea in the night whereas a sea breeze moves the air masses back to the land inside during the day. The wind direction flips very fast from north to south at about 10 a.m. in summer, as shown by Grying.[55] Simultaneously, the dense traffic emits high NO_x concentrations which, together with the strong solar radiation and high temperature, favor ozone production.

DIAL measurements[26,56] were performed in summer 1994 within the large-frame MEDCAPHOT campaign, the LIDAR system being located in the city center (Pnyx Hill). In order to access the ozone formation dynamics, both NO_2 and O_3 mappings were recorded. Figure 12(b) shows the 2-D NO_2 vertical map over Athens at about 10 a.m. Since solar radiation had just started to increase, the NO emitted by the road traffic was oxidized during the early morning (Equations 5 and 6), yielding a thick NO_2 layer near ground level, with concentrations exceeding 100 ppb. Half an hour later, the effect of wind flipping is observed: the sea breeze induces vertical advection of the NO_2 concentration (Figure 12a). The increasing ground temperature also contributes to this rising motion of the air masses.

In Figure 12(a), a secondary local maximum of NO_2 at about 1000 m altitude is clearly observable. This NO_2 is

Figure 12 NO_2 mapping over Athens during a summer smog episode.[26,31]

then photodissociated by the solar radiation, generating ozone (Equations 3 and 4). This leads to the formation of an ozone storage layer, as presented in Figure 13. Ozone concentrations as high as 180 ppb are observed at around 1000 m altitude. Note that the concentration at ground level at this moment is only 50 ppb, owing to the local high NO concentration emitted by the dense traffic.

Figure 13 Ozone storage layer over Athens.[26,31]

Figure 14 Ozone profiles obtained (a) at Seville center, (b) upwind from Seville and (c) 22 km downwind from Seville.[32,33]

The meteorological dynamics take over again at the end of the beginning of the night, when the air masses fall again and transport ozone back to the ground. A detailed study of these dynamics and a comparison with numerical models was described by Weidauer.[56]

The effects of vertical transport of the NO_2-producing ozone observed here can obviously also occur horizontally, in the surroundings of urban areas. The measurements in Seville within the frame of a campaign organised by the Joint Research Center Ispra[33] have been mainly performed at three particularly representative sites. The first series of mappings was recorded in the town center. Profiles were measured along a road with major traffic, interrupted with many traffic lights. Results are presented in Figure 14(a). They show a moderate average ozone concentration of about 50 ppb with peaks at 80 ppb

Figure 14 (*Continued*)

at the beginning of the afternoon when solar radiation is maximum. During the night, the concentration stabilizes around 35 ppb, although it remains important at high altitudes. Again, without solar photodissociation of NO_2, oxidation of nitrogen monoxide takes place, and yields a lower ozone concentration. In other words, as is often observed,[54] the VOC/NO_x in the center of large cities is too low to obtain maximum ozone production.

The second series of measurements was performed in a rural area, La Riconada, upwind from Seville during the measurements. Results are presented in Figure 14(b). Concentrations were low, from 30 ppb during the night to 50 ppb in the day. This can be easily interpreted, since the Seville city plume is propagating in the opposite direction and thus almost no nitrogen oxides (and also O_3) is imported. The population is weakly exposed compared with the population in the center of Seville.

The third site chosen for the LIDAR measurements was downwind from Seville at the measurement time, in a totally rural zone, 22 km from the city. This region is well known for its agricultural production. Long-distance transport of the Seville nitrogen oxides then encounter local biogenic production of VOCs (isoprene, terpene), which yields very favourable VOC/NO_x ratios for ozone production. Moreover, part of the ozone coming from Seville is also transported. This results in a high ozone concentration (Figure 14c) for such a rural site, relatively homogeneous in space and time: 50 ppb on average with peaks at 70 ppb. These concentrations remain high during the night owing to the fact that the local road traffic (and therefore NO) is low.

The results presented here show precisely on the one hand the influence of the meteorological conditions on ozone formation, and on the other hand the importance of transport processes of urban pollution. They also show that some legal reduction actions on nitrogen oxide or VOC emissions may lead to a geographical shift of the ozone maxima and not to an overall reduction.

In the whole discussion above, the effects of aerosols on the ozone production could not be taken into account, since their action is not fully understood. Quantitative measurements of aerosols by LIDAR are thus an important challenge, as described below.

5 DETECTION OF AEROSOLS AND DUST PARTICLES

The impact of atmospheric aerosols on public health and in heterogeneous chemistry is well recognized, although few conclusive studies have been reported so far. This is especially true for urban aerosols, the variety of which in size and composition makes complete characterization difficult. We present here a combined technique, using LIDAR measurements, scanning electron microscopy (SEM), and X-ray microanalysis.[57] Urban aerosols are first sampled using standard techniques on different filters. Their size is determined by SEM and counting and their composition by X-ray microanalysis. The size distribution exhibits mainly two modes: one around 0.1 μm constituted of soot and sulfates and the other around 1 μm composed half of larger soot aggregates and half of silica particles.

These data are then used to compute optical backscattering and extinction coefficients, leaving as the only unknown parameter the total number density of particles. The basis of the determination of the optical scattering coefficients α and β is a newly developed model, based on a fractal theory for small soot particles (from 50 nm to 0.5 μm) and on a modified Lorentz–Mie theory for larger particles such as silica.[58] The larger soot aggregates are considered as spheres made of lacunary media, with 50% carbon and 50% void.

Number-density profiles over Lyon were obtained by simultaneous LIDAR measurements using an eye-safe LIDAR system (frequency doubled Ti : sapphire laser-based system at 390 nm). The LIDAR data were inverted with the backscattering and extinction coefficients computed from the actual size distribution. These measurements were performed in the frame of an intensive campaign in summer 1996 in Lyon, in collaboration with the Departement d'Ecologie Urbaine of the City of Lyon.

LIDAR data were inverted using a Klett algorithm[37,38] with two reference points, one located close to the ground with the α and β values determined above, and the other at high altitude where a clear atmosphere is assumed. In the conditions encountered here, the assumption of an average shape of the size distribution is acceptable (warm, stable afternoon). This could be confirmed by a parallel epidemiological study, involving 30 volunteers with transportable samplers.

Quantitative 3-D distributions of aerosols over the city have been obtained with this method for the first time. The results show a fairly homogeneous mixing layer up to 1300 m. An interesting measurement is also the temporal dependence of the concentrations of these urban aerosols. Figure 15 shows the evolution of the vertical profile of aerosol concentration in Lyon over 24 h during a high-pollution episode, on June 27–28, 1996. It shows very clearly the motion of the mixing layer height. Owing to the temperature changes, the mixing layer top drops to 200 m during the night and rises to 1300 m in the early afternoon. Traffic jams also induce

Figure 15 Temporal evolution of the aerosol mass concentration measured by LIDAR.

an increase in the aerosol density during rush hours, in the morning around 8 a.m., at noon, and in the evening around 6 p.m. Even 80 m above ground, concentrations as high as 40 $\mu g\,m^{-3}$ are observed during these rush hours.

6 VALIDATION OF NUMERICAL MODELS

A task of increasing importance for LIDAR systems is the validation of numerical models. This applies both to microscale dispersion models and to regional-scale codes, which provide output data averaged over grid cells several kilometers long.[54]

Verification of numerical model predictions has been performed both for microscale plume dispersion codes and for regional-scale Lagrangian/Eulerian models during a large frame campaign in the Swiss Rhone Valley.[46] Since both models tested did not include a chemical module, the pollutant chosen for the comparison was a relatively non-reactive species, SO_2.

The verification of the plume spread model was performed on the emission of a power plant, where 3-D mappings of the plume were recorded at high resolution and the concentration was averaged over sections perpendicular to the plume direction. This gave a good estimate of the plume dilution with distance (Figure 16). Owing to the windy meteorological conditions, the emitted SO_2 concentration is rapidly spread and transported in a rather flat plume of about 120 m width for only 30 m height. A typical dilution value is 30 at a distance of 100 m.

Figure 16 Verification of a plume spread model by DIAL measurements.[46]

The model (Micro-EL) is based on the dispersion of a given number of virtual particles and subsequent counting in the grid cells as a function of time. Together with the

meteorological conditions and the emitter characteristics (plume exhaust velocity, temperature, initial SO_2 concentration), one then retrieves the concentration in each grid cell. The agreement between DIAL data and numerical simulations is excellent. This is made possible only through the careful analysis of a very large number of Lagrangean particles (31^3) and the high density of the receptor grid ($1\,m^3$) located along the plume axis in order to estimate dilution. It can be seen, however, that the initial concentrations are overestimated by the numerical model in the vicinity of the chimney exhaust. This difference may be produced by the presence of numerous aerosols (especially water droplets), on which some SO_2 molecules are adsorbed. The SO_2 concentration, measured by DIAL, is then lowered at the benefit of other compounds, which are not measured.

Note also that if the model is verified for some section of the plume, it can be used in turn for the dispersion at longer distances, where DIAL data are no longer available. The LIDAR–model combination can thus be very useful and complementary for long-distance transport studies.

The verification of the large-scale model (MESOCONV[46]) was carried out in the Chablais Valley, a fairly wide channel, completed by several smaller and colder perpendicular valleys, which often leads to a multilayered stable situation. The emitted pollution can therefore be trapped in one of these sublayers without any mixing with the others. The pollution concentration is then highly dependent on altitude, and it is of great importance for vegetation damage to monitor whether the maxima always occur at the same levels above ground. Several SO_2 emitters are present at ground level, and also a highway which follows one of the edges of the valley.

On the day of the experiment, winds were light ($3–5\,m\,s^{-1}$) and blowing down-valley towards Lake Geneva. A very strong temperature inversion was located at about 450 m above the valley floor, at 850 m above sea level. This inversion plays a fundamental role, of course, in the distribution of pollutants within the valley. A comparison between DIAL data and results of the model is shown in Figure 17. For this, vertical profiles, averaged over the horizontal paths across the valley, were both calculated and measured. An excellent correlation was again found at the mesoscale level, under immission conditions. It can be seen that, even for a receptor located some 12 km from the southernmost sources, the value of the peak concentration and its height above the ground correspond very well with the observations. Above the peak value, which is located at the inversion level owing to trapping by thermal stability, as was explained previously, the DIAL system

Figure 17 Comparison between LIDAR vertical profiles of SO_2 measured in the Swiss Rhone Valley and calculated data from a mesoscale model.[46]

detects nonzero pollution which is not computed by the numerical model. This upper-level pollution is in effect a feature of pollution from the previous day which was diffused at height but which remained at upper levels owing to alternating up- and down-valley flow which recirculates the pollutants. The numerical model computed only the contribution to pollution from emissions on the day chosen for this case study, and consequently contains no background pollution, which is a measure of the recent ''history'' of air quality in the region studied. This can be of advantage when attempting to identify the contribution of a particular source to global pollution of multiple origin. Conversely, it may be criticized that the absence of background pollution in the model leads to results which do not correspond to reality.

7 COMPARISON WITH OTHER TECHNIQUES AND CALIBRATION PROCEDURES

Calibration of LIDAR systems is an important but difficult issue, since path-averaged data (within the used spatial resolution) have to be compared with spot reference measurements. Note that the same problem applies to other optical techniques such as open-path FTIR spectroscopy and differential optical absorption spectroscopy (DOAS).

The success of comparative measurements between DIAL and spot reference data depends directly on the concentration gradients present in the atmosphere.[59] In homogeneous conditions, i.e. sites far from emitters, comparative studies can be performed without particular

Figure 18 Comparison between DIAL ozone measurements and data from standard analyzers at different altitudes of a tower.[60]

difficulties. An example of such a study has been performed on ozone by Goers[60] in the forest of Albsfelde (Germany). The LIDAR data were compared with standard analyzer data (UV spectrophotometry) collected at different altitudes on a tower, located 1030 m from the LIDAR system. The laser beam was steered to pass near the tower at the altitude of the 47-m high spot measurement. The results, which are presented in Figure 18, show very good agreement (within $\pm 3\,\mu g\,m^{-3}$) between the LIDAR measurements and standard analyzer data.

Other favorable conditions are emission measurements. The high concentration (at chimney tops, for example) allows DIAL measurements at maximum spatial resolution, which again compare well with the in situ spot data.

Difficult cases are urban conditions. The steep gradients and the concentration levels necessarily require path averaging of fluctuations for the DIAL technique and extremely critical location for the reference analyzers. Comparison strategies therefore have to be carefully developed for these situations. The most critical case is the detection of primary pollutants emitted by road traffic, such as NO. An example of comparison strategies in the latter situation was performed in Stuttgart in 1989 (Figure 19). The spot NO analyzer was located at about 20 m altitude on the top of a building in the city center while the DIAL system beam was directed at it. The observed concentration evolutions as a function of time are remarkably close. However, the absolute concentration values from the DIAL system are still systematically lower by about 15% than the spot data. This is due to the spatial averaging mentioned above, since the LIDAR spatial resolution (50 m) includes lower concentrations from higher altitudes.

Figure 19 Comparison of LIDAR and a spot analyzer in urban conditions for a primary pollutant (NO).

Comparison with spot analyzers is a valuable calibration method but the tests performed on the system are limited to the concentration levels present in the atmosphere during the measurements. An attractive alternative technique is the use of reference gases. A cell is then located in the DIAL measurement path, in which calibrated concentrations of reference gases are introduced. This induces a supplementary absorption in the light path to the absorption from the atmospheric pollutant, and the difference from a second empty cell provides the reference gas concentration. This technique was used very successfully by the Institut National de l'Environnement et des Risques (INERIS) in Verneuil-en-Halatte for the evaluation of commercial DIAL systems.[61,62] The usual normative parameters[63,64] such as detection limit, linearity, repeatability, zero, cross-sensitivity, and interferences, could be determined with this method. As an example, Figure 20 shows the excellent results of the linearity measurement obtained on SO_2. It is important to note that

Figure 20 Calibration of LIDAR systems: results of linearity measurements using a reference gas (SO_2).[61]

similar techniques are used today for the calibration of DOAS and FTIR devices, so that a standard calibration procedure can be determined for all open-path optical methods.

8 NEW LIGHT DETECTION AND RANGING STANDARDS

Advances in technology and the advent of commercial systems recently accelerated the normative actions for DIAL systems. Prenormative activities such as the above-mentioned evaluation by INERIS or campaigns from the European Joint Research Center in Ispra[33] have also greatly supported the norms. Pioneering work was performed by the VDI/DIN commission in Germany from 1992 to 1997, which yielded the first normative text for DIAL systems.[18] A similar action is in progress at the European level for the Commission Européene de Normalisation (CEN). These actions are of crucial importance for the wide use by EPAs of this very attractive technique.

9 CONCLUSION

We have presented an overview of today's capabilities of LIDAR systems to provide 3-D profiles of concentrations of gaseous and particulate pollutants and temporal evolution. New normative actions are recognizing the unique advantages of this technique and show the way to operate and calibrate the available systems properly. More than 20 years after the first LIDAR mappings of gaseous species, the wide use of DIAL systems for monitoring air pollution has today been achieved.

ACKNOWLEDGMENTS

The author wishes especially to acknowledge the work of V. Boutou, M. Douard, B. Vezin, E. Frejafon, J. Kasparian, P. Rambaldi, and J. Yu at LASIM, the group of Prof. L. Wöste at the Free University Berlin, P. Rairoux at the AWI-Potsdam, D. Weidauer and M. Ulbricht at Elight Laser Systems GmbH (Teltow/Berlin), E. de Saeger and B. Ottobrini at the Joint Research Center ISPRA, and T. Ménard and E. Vindimian at INERIS, who all actively participated in one or other of the reported studies.

ABBREVIATIONS AND ACRONYMS

CEN	Commission Européene de Normalisation
DAS	Differential Absorption and Scattering
DIAL	Differential Absorption Light Detection and Ranging
DIN	Deutsche Institut für Normung
DOAS	Differential Optical Absorption Spectroscopy
EPA	Environmental Protection Agency
FTIR	Fourier-transform Infrared
INERIS	Institut National de l'Environnement et des Risques
IR	Infrared
LIDAR	Light Detection and Ranging
NW	North-west
OMA	Optical Multichannel Analyzer
OPO	Optical Parametric Oscillator
PMT	Photomultiplier Tube
RADAR	Radio Detection and Ranging
SE	South-east
SEM	Scanning Electron Microscopy
SHG	Second Harmonic Generation
S/N	Signal-to-noise Ratio
SW	South-west
THG	Third Harmonic Generation
UV	Ultraviolet
UVDIAL	Ultraviolet Differential Absorption Light Detection and Ranging
VDI	Verein Deutscher Ingenieure
VOC	Volatile Organic Compound
2-D	Two-dimensional
3-D	Three-dimensional

Environmental Analysis of Water and Waste: Introduction

Marvin P. Miller
Dow Chemical, Midland, USA

The field of environmental analysis is driven by demand for development of analytical methods providing ever-increasing specificity and throughput, decreases in detection limits, and improvements in precision and accuracy. Typically, meeting these conflicting demands requires a compromise of some type. The methods with the lowest detection limits are seldom those that simultaneously provide the best specificity or most cost effective analysis. Concurrently, the number of analytes of interest in environmental samples continues to expand rapidly while the type and complexity of samples grows as well. Thirty years ago, most environmental analyses were conducted on water samples with perhaps 10–15 analytes per sample. Today samples of interest include water, waste water, soils, solid or liquid waste, and biological materials, and at times the list of analytes to be determined can number several hundred. For these reasons, the variety of analytical methodology utilized for environmental analysis is extensive. The number of approved methods by the United States Environmental Protection Agency (USEPA) alone exceeds several hundred. This section will provide a comprehensive overview of modern environmental methodology for the analysis of water and waste samples. Articles will describe both the application of a wide variety of instrumental methodology, as well as techniques for determination of an extensive array of parameters in many different matrices, including water, waste water, soils, hazardous wastes, and biological materials. Methods specific to field analysis are presented in the section entitled *Field-portable Instrumentation*.

Development of environmental analytical methodology, especially those methods in common usage, has frequently been driven by monitoring regulations and requirements. This is especially true in the United States, where the passage of numerous acts has led to the creation of a variety of target analyte lists. The Federal Water Pollution Control Act or 'The Clean Water Act' (1972) led to lists of analytes to be determined in wastewater discharge streams. As a result of a subsequent law suit, ''N.R.D.C. vs. Train, 8ERC2120'', an extensive list of 129 parameters was established and analysis of this entire list was required for all discharge streams. The Safe Drinking Water Act (1974) resulted in another specific list of 14 parameters that were to be determined in drinking water samples. The Resource Conservation and Recovery Act (1977) and subsequent amendments introduced the Appendix VIII and Appendix IX lists of target analytes for waste and groundwater samples. These list several hundred specific parameters or categories.

In some cases when these lists where first developed, the analytical methodology did not exist to make accurate determinations in the complex matrices of interest. Thus, the legally mandated analyte lists drove the development of more sensitive and selective methods in many areas. Furthermore, enforcement of these laws created tremendous numbers of samples to be analyzed, which created the demand for methods with faster throughput. Thus, the rapid advancements in the field of environmental analytical chemistry and the adoption of sophisticated methodology were in many ways the result of regulatory requirements. For example, early analysis of wastewater samples for many organic species was conducted by a variety of gas chromatographic techniques, requiring several separate analyses to complete one sample. The development of the gas chromatography/mass spectrometry (GC/MS) methods 624 and 625 provided more specific analysis of the organic parameters on the priority pollutant list with only two determinations. Initially, few laboratories had access to expensive, sophisticated GC/MS methods. However, the large volume of samples requiring analysis across the world quickly drove demand for improvements in the instrumentation. Today, GC/MS is relatively inexpensive and is part of every well-equipped environmental laboratory. A similar situation has occurred for the determination of elemental species. The use of inductively coupled plasma (ICP) and ICP coupled with a MS (mass spectrometry) detector (ICP/MS) has greatly enhanced the sensitivity and speed of analysis relative to the use of flame and flameless atomic absorption spectrophotometry.

As is the case in all fields of analytical chemistry, a critical component in environmental analysis is to conduct all determinations under the guidance of a carefully designed quality assurance (QA) program. In many cases, environmental analyses also must be conducted following strictly designed regulatory requirements, dictating such things as sampling and analysis methodology, quality control procedures, and complete documentation policies. Specific legally mandated QA requirements can vary significantly depending upon many parameters, including the country, the regulating agency, and the sample type. While the specific QA requirements can change, the fundamental concepts of QA do not. The introductory article in this section, **Quality Assurance in Environmental Analysis**, written by Malcolm Clark of the Canadian Ministry of Environment, provides a comprehensive discussion of the primary elements of QA. The author covers QA requirements from initial program design through sample collection, analysis, and final reporting. He also discusses

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

types of errors that can occur and means of determining detection limits. The use of certified reference materials, interlaboratory testing and legal QA requirements are discussed, and the author discusses the use of performance based methods, an area of particular emphasis in recent years for the USEPA. Robert Gibbons in **Detection and Quantification of Environmental Pollutants** provides a detailed discussion of a number of means to express detection and quantification data, including applications to limit both false positive and false negative results.

No matter how carefully the environmental analytical chemist conducts the laboratory determination, the quality of the data is totally dependent on the quality of the sample taken. The sample must be representative of the body it represents and it must be maintained in the appropriate manner to prevent contamination and/or deterioration of the analytes of interest. Once again, the vast array of sample matrices and analytes leads to the requirement for many different sampling protocols to meet the above requirements. The following series of articles covers the requirements for sampling in a variety of matrices of environmental interest.

Biological samples can provide an excellent indication of exposure to pollutants, as discussed in **Biological Samples in Environmental Analysis: Preparation and Cleanup** by Steven Barker. Barker further describes means for biological sample preparation and cleanup, including gel permeation, super critical fluid extraction, and solid phase extraction. Sampling for biological monitoring requires additional considerations in order to ensure the appropriate data are collected. **Sampling Considerations for Biomonitoring** are covered by Tim Koeckritz et al. who focus on three key axioms for sampling, i.e. chemical composition, distribution of organisms, and the economic aspects of the information content. While these axioms were developed for biological materials, they are nonetheless relevant with minor modifications to all types of sampling programs.

Soil Sampling for the Characterization of Hazardous Waste Sites is discussed by Brian Schumacher et al. who begin with a discussion of how to plan the sampling program, including definition of the data quality objectives for the program. They discuss considerations for selecting the appropriate spatial sampling strategy and ways to estimate variance. Site mapping, site characterization, and sample collection are described, as well as selection of sampling equipment. **Industrial Waste Dumps, Sampling and Analysis** is the topic of the next article, written by Winfried Rasemann. He discusses some of the basic problems encountered in sampling industrial waste dumps and examples of how these problems can be avoided by statistical evaluations.

Environmental analysis can be divided into three primary categories; organic, inorganic, and 'conventional'. The term conventional is used to describe a variety of determinations that include total carbon, biological oxygen demand, and in some cases ionic determinations by such techniques as ion selective electrode (ISE) or ion chromatography (IC). Asbestos analysis does not fit well in any of these categories, however the widespread use of asbestos in the past and the well-known hazards of exposure makes this a determination of particular interest around the globe.

Norber Hofert discusses the determination of airborne asbestos fibers and asbestos in bulk materials and drinking water in the article **Asbestos Analysis**. The use of scanning, transmission, and phase contrast microscopy is described, as well as the use of X-ray diffraction and infrared techniques.

The determination of total and dissolved organic carbon is one of the most commonly used methods for quickly assessing the overall water quality. Kenneth Mopper and Jian-guo Qian, compare the two primary methods, wet oxidation and high temperature combustion, and examine problems encountered when analyzing sea water in the article **Water Analysis: Organic Carbon Determinations**.

The use of ISEs is widespread in environmental determinations for a large number of analytes. **Ion-selective Electrodes in Environmental Analysis** are described by Robert Forster and Tia Keyes. The authors discuss the advantages of ISEs (portability, sensitivity, wide dynamic range, ease of use, continuous measurement, etc.) They provide a theoretical background for the technique, and a detailed discussion of the various types and applications of ISEs, including determination of metallic species as well as anions and cations. A comprehensive table of analytes and sensitivities that can be achieved with ISEs is provided.

The next series of articles in this section cover the determination of elemental species by a variety of techniques. The series begins with four articles on different sample preparation procedures used on various matrices. First, Sergio Marin discusses **Sample Preparation Techniques for Elemental Analysis in Aqueous Matrices**. Discussions are provided on proper sample collection, handling, and storage, as well as appropriate laboratory conditions for minimizing the potential for contamination. A variety of digestion or extraction procedures are discussed, including wet digestion, dry ashing, sequential extraction, and pressurized digestion. **Sample Preparation for Environmental Analysis in Solids (Soils, Sediments, and Sludges)** is described by D. Kimbrough beginning with a discussion of ways to physically prepare the samples (milling, sieving, etc.). Kimbrough reviews several USEPA acid digestion procedures and discusses the application of each to different matrix types. He also describes methods for extraction of organic compounds from solids using solvent extraction.

The preparation of biological samples for elemental analysis requires special consideration and is described by Kunnath Subramanian in the article entitled **Sample Preparation for Elemental Analysis of Biological Samples in the Environment**. Protein precipitation, chelation, and solvent extraction are discussed, as well as a variety of procedures to remove the organic matter from the samples. Specific considerations are provided as a function of the element of interest, the sample matrix (e.g. urine, hair, bone, tissue), and the instrumentation to be used (e.g. ICP, ICP/MS). Mehdi Ashraf-Khorassani, Larry Taylor and Michael Combs, provide their insight on the use of **Supercritical Fluid Extraction of Inorganics in Environmental Analysis**. While direct extraction of cationic metal ions is not feasible with supercritical CO_2, in situ chelation of the metal ions can enhance the extraction efficiency. The authors examine the solubility of different ligands and metal chelates in supercritical fluids and assess the impact of the matrix as well.

The next series of articles covers a variety of instrumental techniques used for the determination of elemental species. Perhaps the most commonly used, and certainly the instrumental technique that has the longest history, is the use of atomic absorption spectroscopy (AAS), both by flame and graphite furnace. This topic is covered extensively by Michael Sperling, **Flame and Graphite Furnace Atomic Absorption Spectrometry in Environmental Analysis** starting with a comparison of detection limits for both flame and furnace AAS. Sperling provides a very useful summary of instrument fault recognition and means for optimization of the instrument. Spectral and nonspectral interferences and AAS specific QA are described. Sperling follows with a comprehensive discussion of the application of both flame and furnace AAS for analysis of waters, soils and other solid materials.

For certain elements with higher volatility (e.g. arsenic, selenium), conventional flame and furnace AAS techniques may not provide adequate sensitivity for some environmental concerns. One means to improve the sensitivity for these parameters is by use of hydride generation for sample introduction. Hisatake Narasaki discusses in **Hydride Generation Sample Introduction for Spectroscopic Analysis in Environmental Samples**, including proper sample preparation, detection limits and application to not only AAS but also both optical emission ICP and ICP/MS.

Scott Baker and Nancy Miller-Ihli describe another sample introduction technique that can be used to enhance sensitivity, particularly for solid samples, **Slurry Sampling Graphite Furnace Atomic Absorption Spectrometry in Environmental Analyses**. The use of slurry sampling into the graphite furnace is described, including methods for producing and optimizing slurries of a variety of matrix types. Instrumental conditions are described and examples of environmental applications are given, as well as comparisons to other direct analysis methods.

The determination of mercury is of particular interest due to its toxicity and propensity to bio-accumulate. Unfortunately, neither flame nor graphite furnace AAS can provide a detection limit adequate for determination of mercury at levels of environmental concern, typically in concentrations of low to sub-part per billion. The most commonly used technique **Mercury Analysis in Environmental Samples by Cold Vapor Techniques**, is discussed here by Kim Anderson. The author describes the sample preparation technique, and the use of the specific instrumentation required, as well as sensitivities and common interferences. The sensitivity of cold vapor (CV) AAS is compared with other potential techniques, such as atomic fluorescence spectroscopy (AFS), and a summary of mercury regulatory standards around the world is given.

While AAS is an extremely valuable technique, the throughput is limited, particularly when using the graphite furnace. The introduction of inductively coupled plasma atomic emission spectroscopy (ICPAES) led to the rapid advancement of methodology to take advantage of the simultaneous multi-elemental analysis capability while providing detection limits equivalent or better than graphite furnace AAS. **Optical Emission Inductively Coupled Plasma in Environmental Analysis** is described by Mark Tatro. The author outlines available USEPA ICPAES methods and discusses means for overcoming common interferences. ICPAES specific QA requirements are also described.

In some cases, even ICP optical emission spectroscopy cannot provide sufficient sensitivity or specificity for certain elements in certain matrices. For example, optical ICP generally cannot be used for determination of arsenic, selenium, and mercury in drinking water samples because the detection limits are not adequate. The development of ICP coupled with a mass spectrometer as a detector provides an additional tool with enhanced sensitivities for many elements. **Inductively Coupled Plasma Mass Spectrometry in Environmental Analysis** is described by S. Yamasaki who reviews the instrumentation and provides an overview of the types of sample introduction used with ICP/MS. The typical detection limits are provided for elemental analysis of environmental samples in water, soils, and biological materials. The author also describes the use of high resolution ICP/MS which can be used to provide enhanced selectivity.

The determination of specific elemental forms is described by Wang Xiaoru and Frank Sen-Chun Lee, in their contribution entitled **Capillary Electrophoresis Coupled to Inductively Coupled Plasma-Mass Spectrometry for Elemental Speciation Analysis** (CE/ICP/MS). The authors describe optimization of the capillary

electrophoresis (CE) separation procedure and compare the technique to conventional ICP/MS. A comparison is made of a number of nebulizers that have been used for CE/ICP/MS.

Conventional ICP or ICP/MS analysis requires the dissolution of the sample for introduction into the instrument as a solution. In addition to the time required for sample preparation, the dissolution can result in decreased sensitivity. **Laser Ablation Inductively Coupled Plasma Spectrometry in Environmental Analysis**, as described by Steven Durrant, can provide a means for the direct vaporization of a solid sample and subsequent introduction into either an optical ICP or ICP/MS. The author describes several laser ablation systems and provides analysis procedures, including its use for samples of environmental interest, such as metals, geological, and biological materials.

In some cases, it is of interest to detect organic species containing specific elements. Stig Pedersen-Bjergaard has provided an article on **Gas Chromatography with Atomic Emission Detection in Environmental Analysis**. The column first separates the organic species and the elemental detector can be tuned to the parameter of interest. The author describes the selectivity and sensitivity of the method, as well as a compound independent calibration. He provides examples of several environmental applications for compounds containing specific elements such as tin, lead, and mercury, as well as the use for other compounds containing non-metallic elements.

Yong Cai discusses the use of another alternative technique for elemental analysis, **Atomic Fluorescence in Environmental Analysis**. AFS can provide enhanced detection limits for some elements, and is of particular interest for the ultratrace level determination of mercury. In AFS, the sensitivity is directly proportional to the intensity of the light source, thus the author describes the use of hollow cathode lamps, electrodeless discharge lamps, xenon arc lamps and lasers. The determination of mercury by AFS is covered in detail, including methodology for organometallic determination of mercury species. Hydride generation is also described as a means to further enhance sensitivity and selectivity for volatile elements such as arsenic and selenium.

Flow-injection Techniques in Environmental Analysis are described by J.L. Burguera and M. Burguera. The authors describe how flow injection spectrophotometric methods can be used as alternatives to AAS and ICP techniques. In addition, the authors describe how flow injection can be used in conjunction with other instrumental methods such as AAS or ICP. A comprehensive list of the use of flow injection in environmental analysis is provided.

A recent addition to the tools used in environmental analysis for separation of complex samples, CE, is discussed by Yang Sun Kim in the article **Inorganic Analysis in Environmental Samples by Capillary Electrophoresis**. The author outlines the use of this technique for environmental samples, specifically for the determination of anions, metal speciation, metal complexes, and organometallic compounds. Comparison is also made with alternative methods such as IC, ICP and ICP/MS.

Inorganic Environmental Analysis by Electrochemical Methods offers an alternative to the commonly applied spectroscopic methods for the determination of many elements in a variety of matrices. This technique is discussed by Guler Somer. Polarographic and voltametric methodology is covered, and application to air, drinking water, rivers, lakes, sea water, and wastewater, as well as for soil and sediment, is reviewed.

The determination of inorganic anions, cations, transition metals and low molecular weight organic acids and bases by IC is described by Peter Jackson in the article entitled **Ion Chromatography in Environmental Analysis**. The author provides a brief history of the technique and a comparison with alternative methodology. Sampling handling, preservation, preparation and clean-up are described, and the use of IC in regulatory methods is covered, including specifics for inorganic anions, hexavalent chromium, cyanide and others. The use of IC for a variety of matrix types such as water, brines, soils, and sludge, is discussed.

Neutron activation analysis (NAA) provides excellent sensitivity, multi-element capability, ease of sample preparation, and freedom from interferences. However, it also requires access to a reactor facility in order to irradiate the samples. This powerful technique is discussed by Keith Randle, in **Neutron Activation in Environmental Analysis**. The author provides a brief history of the technique, followed by a discussion of the use of NAA for environmental samples with a table of ideal sensitivities. Application to biological samples is also discussed. The focus of the article is on the analysis of water samples by NAA, as well as the analysis of soils and sediments.

Another alternative technique for the determination of elements in environmental is samples is **Proton-induced X-ray Emission in Environmental Analysis**, or PIXE. Like NAA, PIXE provides simultaneous determination of a large number of elements and high throughput. However, as described by Grazia Ghermandi, in order to achieve sensitivities of environmental interest, a pre-concentration technique is frequently required. The author describes the methodology and its application to environmental samples such as water, sediments, and atmospheric aerosols. Matrix effects and interferences are discussed, as well as typical detection limits and

ranges for a variety of elements. The author also outlines the procedure to follow to develop a method for environmental analysis using PIXE.

X-ray Fluorescence Spectroscopic Analysis of Liquid Environmental Samples is the title of the next article, written by Philip Russell. The author includes descriptions of energy dispersive (EDXRF), wavelength dispersive (WDXRF), and total reflection X-ray fluorescence (TRXRF) and their use in the elemental analysis of natural waters, waste waters, hazardous wastes, and samples of interest to the nuclear industry. A section is also included on development of both EDXRF and WDXRF methods and on comparison with other spectroscopic methods.

Heavy Metals Analysis in Seawater and Brines is of particular interest due to the desire to study bioaccumulation of these parameters. However, because of the high salt content of the matrix, special procedures have been developed to minimize the matrix affects. Osvaldo Troccoli reviews this topic. Preconcentration and separation are described, as well as the most commonly encountered interferences observed using atomic spectroscopic techniques. A comparison is given among the spectroscopic procedures and electrochemical methods.

The primary focus of the determination of elements in environmental samples continues to be on the determination of the total amount of the element present, regardless of the oxidation state or the specific compound present. However, as more information has become available on the significant variation in toxicity of different organometallic compounds containing the same element of interest, methods have been developed to determine specific organometallic compounds as they occur in the environment. **Organometallic Compound Analysis in Environmental Samples** is addressed by Les Ebdon and Andy Fisher. The authors describe specific issues that must be considered when collecting and storing samples for subsequent analysis for organometallic compounds. Sample preparation procedures are given to extract the analyte of interest from liquid or solid samples. In some cases, a derivatization technique may be required in order to ensure that the analyte is in the appropriate form. A variety of analysis techniques are described, including both GC (gas chromatography) and LC (liquid chromatography) coupled with atomic spectrometry, and CE coupled with atomic spectroscopy. QA requirements specific to organometallic analysis are also discussed.

The overall characteristics of soil quality and a summary of soil analysis methodology is provided by M.R. Carter et al., in their article entitled **Soil Instrumental Methods** The authors describe proper soil sampling procedures and statistical sampling methods, as well as discussing chemical, biochemical, and physical testing procedures.

As is the case for inorganic parameters, the determination of organic species of environmental interest frequently requires some means of specialized sample preparation in order to separate the analyte of interest from complex matrices. The first article in this section of sample preparation, **Soxhlet and Ultrasonic Extraction of Organics in Solids**, contributed by G.R. Barrie Webster, provides a comparison of two primary extraction procedures for solid materials, ultrasonic and Soxhlet extraction. A comparison is made between USEPA methods and alternate procedures and specific QA and trouble shooting considerations are discussed.

Another alternative extraction procedure for organic species is discussed in the article, **Solid-phase Microextraction in Environmental Analysis** is provided by J. Pawliszyn. Two distinct solid phase microextraction (SPME) coating types are discussed, and a theoretical description of their use is given. The use of SPME for field analysis with a portable GC to determine volatile organic compounds (VOCs) in groundwater, soil, and air. Field evaluations of recently developed prototype systems are described.

The use of microwave energy to assist in solvent extraction of organic species is the topic of two articles. First, Frank Smith and Guohua Xiong have contributed the article entitled **Microwave-assisted Techniques for Sample Preparation in Organic Environmental Analysis**. The authors provide an extensive review of the use of microwave assisted extraction for a wide variety of organic parameters of environmental interest in soils, sediments, plant tissue, air and aqueous matrices. They also cover the use of focused microwave assisted Soxhlet extraction, microwave heating headspace analysis, and microwave-assisted derivatization. John Dean in his article entitled **Microwave-enhanced Solvent Extraction of Organics in Environmental Analysis**, discusses the theoretical basis of microwave extraction of organic analytes and describes both atmospheric and pressurized microwave extraction techniques. Comparisons are made with Soxhlet, ultrasonic, and supercritical fluid extraction (SFE) for polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), and pesticides in standard reference materials and other samples.

In the article, **Supercritical Fluid Extraction of Organics in Environmental Analysis** Bruce Benner provides a theoretical discussion of supercritical fluids and their use for extraction of organic species from complex matrices. Reviews of several models of the supercritical extraction process are given, followed by a description of the instrumentation commonly used for SFE. An extensive review of the use of SFE for a wide range of organic classes is provided, including PCBs, pesticides, PAHs,

and hydrocarbons. Studies of extractions conducted on standard reference materials are discussed, comparing SFE with other extraction procedures.

Membrane-based non-chromatographic continuous separation techniques can also be used in environmental analysis for increased selectivity. **Pervaporation, Analytical** by M.D. Luque de Castro and L. Gamiz-Gracia reviews the principles of pervaporation and its use in analytical separation. The laboratory scale pervaporator is described, including a discussion of various membranes that can be used for different analytes. The sensitivity and selectivity of pervaporation is compared with headspace analysis and systems for multi-determinations are described.

GC is likely the most commonly used methodology for the determination of organic species in environmental samples. The need to determine a variety of classes of organic compounds at very low concentrations in frequently very complex matrices has led to the development of many selective detectors, each with specific advantages for certain compound classes. In **Trace Organic Analysis by Gas Chromatography with Selective Detectors**, Erwin Rosenberg provides a review of selective GC detectors, including electron capture, nitrogen-phosphorus, flame photometric, photoionization, and electrolytic conductivity (Hall) detectors. The operating principles and applicability of each type are discussed, as well as relative sensitivities. The author also provides a review and comparison of mass spectrometric, Fourier transform infrared, and atomic emission detectors for GC. Hiroyuki Kataoka provides specific focus on the use of selective detectors for the determination of amines in **Gas Chromatography with Selective Detectors for Amines**. The use of thermionic, flame photometric, electron capture, chemiluminescence, electrolytic conductivity, and mass selective detectors for various amine compounds is reviewed, with comparisons of sensitivities and applicability to aliphatic, aromatic, heterocyclic, and nitrosamines.

Most methods for the determination of organic compounds in aqueous samples requires some means of pre-separation from the matrix, such as solvent extraction, headspace analysis, or solid phase extraction. However, some water soluble analytes cannot easily be separated by these means, or it may be desirable to limit alteration of the matrix. Marek Biziuk has contributed **Gas Chromatography by Direct Aqueous Injection in Environmental Analysis**, a method requiring no separation prior to analysis. The author reviews techniques for direct aqueous injection onto both packed and capillary columns, including discussions of selectivity, sensitivity, and applicability. On column injection is discussed, including application to determination of haloforms in water using electron capture detection. Data are provided for the use of direct aqueous injection in determining organohalogen parameters in tap, surface and swimming pool waters, and for the determination of semivolatile and nonvolatile compounds.

While GC can be used with a variety of selective detectors to provide excellent sensitivity, in some cases the selectivity is not sufficient for positive identification of specific analytes due to the potential for co-elution of multiple compounds, even with the excellent resolution of modern capillary columns. By using a mass spectrometer as a detector for GC, another dimension is provided, allowing identification based on unique mass fragmentation patterns. **Trace Organic Analysis by Gas Chromatography with Quadrupole Mass Spectrometry**, contributed by Matthew Booth and David Powell, provides a review of the history of the development and use of GC coupled to quadrupole MS. The two principle methods of ionization, electron and chemical, are described, and sample preparation techniques for volatile and semivolatile analytes are reviewed. Special considerations are given for the use of GC/MS instrumentation.

While GC/MS is a very powerful technique for the determination of volatile and semi-volatile compounds, many organic compounds of environmental interest cannot be determined because they are non-volatile, polar, thermally labile, or ionic. M. Careri discusses the coupling of LC to MS, in **Liquid Chromatography/Mass Spectrometry in Environmental Analysis**. The author reviews types of instrumentation used for LC/MS, LC/MS/MS (tandem mass spectrometry) and LC/ICP/MS and their application for the environmental determination of pesticides, PAHs, dyes, surfactants, and organometallic compounds.

Organic acids are wide spread in the environment, and cannot be determined at trace levels via GC methods. Sigrid Peldszus has provided **Organic Acids Analysis in Environmental Samples, Ion Chromatography for Determination of**. The author reviews sources and samples of interest for organic acids, such as drinking water, waste water, and landfill leachates. The application of IC is discussed and sampling and preservation procedures are provided for various matrices. Specific sample preparation and analysis procedures are reviewed for air, drinking water, wastewater, and ground water samples, and comparison of IC with other methods or analysis of organic acids is given.

The next four articles describe alternate analytical methodologies that can be applied for the determination of organic analytes in environmental samples. Tom Viser has provided **Infrared Spectroscopy in Environmental Analysis**, where the author reviews application of infrared analysis to determination of a variety of VOCs in indoor air, atmospheric, and stack samples. In **Organic Analysis in Environmental Samples by Capillary Electrophoresis**,

Carmen Garcia-Ruiz et al. describe the use of CE for the separation of ionic compounds with low molecular weight and sufficient water solubility, compounds typically difficult to determine by conventional GC techniques. The use of CE for the determination of herbicides, phenols, amines, dyes, and aromatic sulfonic acids are described. In **Organic Analysis in Environmental Samples by Electrochemical Methods**, Ignacio Naranjo-Rodriguez and Jose Luis Hidalgo-Hidalgo de Cisneros describe the use of differential voltammetry, stripping methods and electrochemical detection. The authors outline the use of electrochemical detection in regulatory methods in the US and Europe, and provide specifics for determination of aromatic amines, aromatic hydrocarbons, phenols, PCBs, and other nitrogen containing compounds. Janet MacFall and Tony Riberio describe the use of nuclear magnetic resonance (NMR) spectrosopy in **Nuclear Magnetic Resonance for Environmental Monitoring**. NMR can be used for direct determination of samples, such as plants and soils, for analytes including pesticides, phosphorus, and water. Field application for study of soils is also described.

Analysis of organic compounds in the environment can also be categorized by compound class. The following series of articles reviews methodology for the determination of organic compound classes of particular environmental concern. In **Trihalomethanes in Water, Analysis of**, Louis Lepine and Roland Gilbert compare the primary analytical methods used for determining trihalomethanes in drinking water, key regulated analytes resulting from water disinfection with chlorine. The authors compare direct aqueous injection GC, liquid–liquid extraction with GC analysis, headspace GC, and purge and trap GC. An alternative disinfectant to chlorine for drinking water is the use of chloramine, frequently used to reduce the formation of trihalomethanes. However, chloramine can lead to the formation of cyanogen chloride, as discussed by Yuefeng Xie and Cordelia Hwang, in their article, **Cyanogen Chloride and Cyanogen Bromide Analysis in Drinking Water**. The authors outline the use of purge and trap GC/MS, headspace GC with electron capture detection, and liquid–liquid extraction methods.

Billions of pounds of dyes are used globally each year, as discussed by J. Riu and D. Barcelo in their submission entitled **Dyes, Environmental Analysis of**. Because of the nonvolatile nature of most dyes, LC/MS is commonly used for their analysis. The authors discuss thermospray LC/MS applications and the use of atmospheric pressure ionization interfaces. CE is also discussed for analysis of sulfonated azo dyes.

In his paper, **Explosives Analysis in the Environment**, Bruce Tomkins, describes the use of liquid–liquid extraction followed by high-performance liquid chromatography (HPLC) analysis for the determination of explosives in aqueous samples and reviews the use of USEPA Method 8330 for the determination of explosives in soils. Field screening techniques, such as colorimetric and antibody based tests, are evaluated and the metabolism of explosives in the environment are reviewed. Torsten Schmidt et al. review the **Nitroaromatics, Environmental Analysis of**. The relevant USEPA and other regulatory agency methods are cited and their application discussed. Sample preparation procedures for water, soil, and particulate samples are reviewed. In situ analytical methods including electrochemical, immunoassays and sensors are described, as well as laboratory analysis via GC, GC/MS, and HPLC.

Formaldehyde, Environmental Analysis of is reviewed by S.S. Srivastava and K. Maharaj Kumari. Colorimetric spot test, titrimetric, polarographic, and chromatographic methods, including GC, GC/MS, and HPLC, are discussed, as well as infrared and Fourier transform infrared analysis for formaldehyde in air samples.

Phenolic compounds are found both in nature and from industrial production, and phenol itself has been used as a disinfectant since 1865. Monika Moeder in **Phenols Analysis in Environmental Samples**, discusses the uses and toxocologic importance of phenols and regulations impacting their use and disposal. The commonly used analytical techniques for phenol determination are reviewed, including GC/FID (gas chromatography/flame ionization detector), GC/ECD (gas chromatography/electron capture detection), and GC/MS. The author also reviews the colorimetric method commonly used for determination of phenols as a group, normally referred to as 'total phenol'. The application of different sample preparation procedures to various matrices is discussed and conventional techniques are compared with new developments in biosensors and immunoassay.

Michael Fisher and Israel Schechter have contributed a review of **Polynuclear Aromatic Hydrocarbons Analysis in Environmental Samples**, beginning with a definition of PAHs and their importance in the environment. Various extraction procedures, including Soxhlet, ultrasonic, supercritical fluid, and microwave assisted are reviewed for use in PAH analysis, followed by solid phase extraction and gel permeation chromatography clean-up procedures. Analysis by GC, HPLC, GC/MS, and optical methods is discussed, as well as recent procedure utilizing immunoassay techniques. Andres D. Campiglia reviews the determination of PAHs by luminescence techniques, in the article entitled **Luminescence in Environmental Analysis**. The author compares fluorimetry, phosphorimetry, and Shpol'skii spectrometry and their use for the determination of PAHs both in the laboratory and using laser excitation for field and remote analysis.

Another group of organic compounds of common interest in environmental analysis is the PCBs, consisting of 209 separate isomers. This topic is reviewed in **Polychlorinated Biphenyls Analysis in Environmental Samples** by Bert van Bavel et al. The authors provide a short history of PCB analysis in environmental samples and discuss the two most commonly used analytical methods, GC with electron capture detection and GC/MS. Procedures are reviewed for sample clean-up and fat removal and for sample extraction from a variety of matrices. Recent developments in SFE coupled to LC and GC coupled to time of flight MS are also reviewed.

The ability to rapidly determine parameters of environmental interest, especially in the field, is of particular interest both to provide direction in sampling of potentially contaminated sites and to minimize the number of samples requiring more time consuming and costly analysis back in the laboratory. The next three articles provide insight into recent developments in techniques for rapid deployment in the field. First, in **Volatile Organic Compounds in Groundwater, Probes for the Analysis of**, B.M. Patterson and G.B. Davis describe the use of VOC probes for the determination of petroleum products and chlorinated solvents in groundwater in the field. The authors provide a review of alternative field methods for VOCs and comparison with the VOC probes, based on a coil of silicone tubing, are given for actual field samples. The advantages of the VOC probes include exclusion of high molecular weight organic compounds from the sample, elimination of the need to collect, transport, and store samples, and higher sensitivity vs. conventional methods. Disadvantages include a lack of specificity due to the nature of the sensor currently used.

The analysis of dioxin and similar compounds has been of primary interest to the environmental analyst for a number of years. Traditional methods of analysis require extensive sample clean up and pre-concentration techniques, followed by highly specific GC/MS analysis, in order to attain the detection limits required for this class of compounds. Nigel Bunce and John Petrulis describe an alternative screening technique in their article entitled **Dioxin-like Compounds, Screening Assays**. The use of bioassay methodology, such as receptor-ligand binding assays, saturation assays, gel retardation assays, competition assays, and others are described and their applications for the determination of dioxin like compounds are reviewed. While bioassays cannot replace direct analysis techniques due to the lack of chemical identification, they can provide rapid, expensive screening to help eliminate negative samples from requiring further analysis. Barry Lesnik in **Immunoassay Techniques in Environmental Analyses**, discusses the broader application of immunoassay techniques. The author describes the USEPA interest in these rapid screening methods and provides a background on the development of methods within the USEPA in general and for immunoassay methods in particular. The use of enzyme linked immunosorbent assay (ELISA) for the determination of PCB contamination is described, including a discussion on specificity. Alternative immunoassay techniques are described for determination of dioxins, furans, PAHs, and explosives. Specific considerations for immunoassay method development are presented as well as method validation criteria and a summary of current USEPA methods development programs.

Determination of whether or not a waste is hazardous is of key interest in determining appropriate disposal procedures. Several methods have been developed by the USEPA and others in order to classify wastes as hazardous. In **Waste Extraction Procedures**, Barton Simmons describes the history of the development of waste characterization procedures, including the Extraction Procedure and subsequent Toxicity Characteristic Leaching Procedure. Leachate preparation and analysis is described, including the use of the zero headspace extractor. The author also describes alternative waste characterization procedures, including the Synthetic Precipitation Leaching Procedure, batch, sequential, and multiple extraction techniques. Limitations encountered with various waste extract procedures are also discussed.

The final article of this section, entitled **Underground Fuel Spills, Source Identification**, was contributed by Barry K. Lavine et al. The widespread use of underground fuel storage tanks throughout the USA has lead to numerous problems with leakage and subsequent contamination of groundwater and drinking water supplies. The authors describe the pattern recognition process used to categorize spills, and its use for fuel spill identification, incorporating principal component analysis to reduce the number of independent variables. Case studies are provided to demonstrate the use of the pattern recognition techniques to identify the source of jet fuel spills, based on GC analysis of the samples.

ABBREVIATIONS AND ACRONYMS

AAS	Atomic Absorption Spectroscopy
AFS	Atomic Fluorescence Spectroscopy
CE	Capillary Electrophoresis
CE/ICP/MS	Capillary Electrophoresis Coupled to Inductively Coupled Plasma-mass Spectrometry
CV	Cold Vapor
EDXRF	Energy Dispersive X-ray Fluorescence
ELISA	Enzyme Linked Immunosorbent Assay
GC	Gas Chromatography

GC/ECD	Gas Chromatography/Electron Capture Detection
GC/FID	Gas Chromatography/Flame Ionization Detector
GC/MS	Gas Chromatography/Mass Spectrometry
HPLC	High-performance Liquid Chromatography
IC	Ion Chromatography

The comprehensive use of asbestos in approximately 3000 industrial applications in the past requires asbestos analysis at present and in the future. The different analysis methods range from simple and cost-effective procedures in order to decide whether asbestos is present up to the expensive and time-consuming determination of low fiber number concentrations of asbestos fibers including the identification of the fiber type using highly sophisticated measurement equipment.

The following survey discusses the most relevant objectives of asbestos analysis and the measurement techniques that are applied:

- *Ambient/indoor air measurements – low concentration range, fiber type usually not known, identification required – using transmission electron microscopy (TEM) in combination with energy-dispersive X-ray analysis (EDXA) and selected area electron diffraction (SAED), and using scanning electron microscopy (SEM) in combination with EDXA.*
- *Workplace air measurements – low to high concentration range, fiber type usually known, identification possibly required – using SEM, TEM, and phase contrast optical microscopy (PCOM).*
- *Stationary source emission measurements using SEM, TEM, and PCOM.*
- *Bulk material analysis – usually qualitative measurements; semiquantitative or quantitative results possible, if required – using SEM, TEM, infrared (IR) spectroscopy, PCOM, polarized light microscopy (PLM), and X-ray diffraction (XRD).*
- *Water analysis using TEM.*

1 INTRODUCTION

The combination of ideal technical properties (heat resistance, noncombustibility, high tensile strength, flexibility, resistance to chemical agents) has favored the use of asbestos in approximately 3000 industrial applications so that it plays an important role in modern civilization. These applications have been widely used because asbestos is an abundant, relatively inexpensive and nearly indestructible material, having unique properties that made it readily adaptable to a variety of physical forms and applications. Applications of asbestos comprise numerous building materials (for example loose-fill insulation, acoustic and thermal sprays, pipe and boiler wraps, flooring and roofing materials, cementitious products), friction plates, sealings, gaskets, heat-resistant clothing, adhesives, paints, coatings, etc.

Asbestos is the commercial term applied to the asbestiform varieties of six different silicate minerals. The asbestiform habit causes them to be easily separated

Table 1 Asbestos varieties, ideal composition and CAS registry numbers

Name	Ideal composition	CAS number
Chrysotile	$Mg_3Si_2O_5(OH)_4$	12001-29-5
Amosite	$(Fe,Mg)_7Si_8O_{22}(OH)_2$	12172-73-5
Anthophyllite	$(Mg,Fe)_7Si_8O_{22}(OH)_2$	77536-67-5
Crocidolite	$Na_2(Fe,Mg)_3Fe_2Si_8O_{22}(OH)_2$	12001-28-4
Actinolite	$Ca_2(Fe,Mg)_5Si_8O_{22}(OH)_2$	77536-66-4
Tremolite	$Ca_2(Mg,Fe)_5Si_8O_{22}(OH)_2$	77536-68-6

into long, thin, flexible, and strong fibers when crushed or processed. The names, ideal composition and Chemical Abstracts Service (CAS) numbers of these varieties are given in Table 1. Chrysotile is a fibrous mineral variety of serpentine. The five other asbestiform varieties belong to the amphibole group. The most important asbestos type is chrysotile, with about 94% of the worldwide production. Crocidolite has a share of 3–4% and amosite approximately 2% of the worldwide asbestos production. The other types play no significant role.

Industrial manufacturing of asbestos commenced in the middle of the nineteenth century. It was much later when medical research revealed the casual relationship between the inhalation of asbestos fibers and several severe diseases. Inhaled asbestos fibers can affect human health by causing conditions such as asbestosis and the growth of malignant tumors such as mesothelioma or lung cancer. Asbestos is now considered to be a costly mineral when all subsequent costs for its removal and occupational disease-related expenditure are taken into account. The health risks of asbestos fibers have highlighted the need for efficient measurement techniques.

Medical evidence indicates that the numerical fiber concentration, the fiber size, and the fiber type (biopersistence) are the relevant parameters for the evaluation of inhalation hazards. Fibers longer than 5 μm, narrower than 3 μm and with an aspect ratio greater than 3 : 1 are considered to be critical. A fiber counting and measuring technique is the logical approach, i.e. using microscopy methods. If positive identification of the fiber type is required, the only possible method is electron microscopy in combination with other identification systems, in order to discriminate between asbestos and nonasbestos fibers (for example naturally occurring or man-made mineral fibers (MMMFs)).

A variety of methods, using technical equipment of different levels of complexity and investment (operating) costs, have been developed to satisfy the recent requirements of science and legislation:

- comparison with exposure limits;
- monitoring airborne fiber concentrations (ambient air, indoor air, stationary source emissions);
- final clearance monitoring in connection with asbestos abatement in buildings;
- bulk material analysis.

In order to provide comparability between measurements, standard methods are required. This report only deals with methods that have undergone or will undergo future standardization by a national or international standards organisation (e.g. International Organization for Standardization (ISO)) or other institutions with regulation purposes (e.g. World Health Organization (WHO), United States Environmental Protection Agency (USEPA), Verein Deutscher Ingenieure (VDI)). Specific applications, as for example the determination of asbestos fibers in lung tissue, are not dealt with. Table 2 gives a survey of the proven and established methods.

2 OBJECTIVES OF MEASUREMENT

The following objectives are relevant for asbestos analysis:

Table 2 Proven and established methods for asbestos analysis

Method	Fiber specific	Method of identification	Limitations	Detection limit achieved
Microscopy methods				
PCOM	Yes	–	Visibility for fiber width ≥ 0.2 μm	About ≥10 000 fibers per cubic meter
PLM	Yes	Refractive index	Identification only for fiber widths ≥ 1 μm	About ≥10 000 fibers per cubic meter
SEM	Yes	Elemental composition by EDXA	Identification only for fiber widths ≥ 0.2 μm	≥300 fibers per cubic meter[a]
TEM	Yes	EDXA and crystallographic structure by SAED (electron diffraction, ED)	Theoretically no limits	For structures of length >0.5 μm about ≥2500 fibers per cubic meter[a] at magnification of 20 000 and indirect transfer
Other methods				
XRD	No	XRD	Only for bulk materials	≥1% in weight
IR	No	IR absorption	Mainly for bulk material samples, also possible for emissions from stationary sources	≥1% in weight

[a] The detection limit can be varied when varying the analysis conditions (e.g. the evaluated filter area).

1. Concentration (fibers/per cubic meter) of airborne asbestos fibers:
   (a) assessment of concentrations of airborne fibers in workplace atmosphere (comparison with occupational exposure limits; most commonly personal exposures);
   (b) assessment of concentrations of airborne fibers in ambient air (background concentrations);
   (c) assessment of concentrations of airborne fibers in emissions from stationary sources (assessing the effectiveness of process-control techniques and monitoring the effects of process modifications);
   (d) assessment of concentrations of airborne fibers in indoor air – sources of contamination, status quo measurement, assessment of the progress of abatement measures, final clearance monitoring;
   (e) epidemiology.
2. Mass concentration (milligrams per cubic meter) of asbestos fibers:
   (a) assessment of concentrations of airborne fibers in workplace atmospheres (most commonly personal exposures);
   (b) assessment of concentrations of airborne fibers in emissions from stationary sources.
3. Indicative or qualitative determination of asbestos in bulk materials.

Today the greater part of measurements for asbestos analysis concerns indoor air measurements, workplace measurements, and bulk sample analysis. Ambient air measurements no longer play a significant role in countries where the use of asbestos has been drastically restricted by law. The situation may be different in countries with lower restriction levels.

3 DETERMINATION OF AIRBORNE ASBESTOS FIBERS

3.1 General

Measurement tasks that can be solved by a pure fiber count commonly use PCOM. Such situations are frequently observed in workplace atmospheres of asbestos processing industries, where most fibers are asbestos.

In cases where identification of fiber type is needed the PLM technique can be used so long as the fibers are wider than about 1 μm.

Electron microscopy techniques (SEM, TEM) are more expensive but they provide additional information on fiber type. SEM, in conjunction with EDXA, can generally be used to determine the elemental composition of fibers wider than about 0.1 μm. The most expensive method, TEM, is generally acknowledged as the most accurate technique for characterizing crystalline inorganic fibers and can be used to provide chemical and structural information for fibers down to about 0.01 μm in width. The results of the different microscopical methods, which provide fiber concentrations, are not directly comparable, because the methods differ in sample preparation and evaluation, and partially in fiber counting rules.

Each measurement technique used gives an index for the numerical concentration of a certain fiber type. Some techniques may give lower counts, resulting from lower visibility caused by lower magnification or resolution; some may give higher counts due to false positive identification connected with the limits of the identification method used. Some problems related to the use of automatic image analysis systems for fiber counting purposes have yet to be resolved, so that this modern technique cannot yet replace the microscope operator.

The technical specifications and a detailed description of sampling, sample preparation, and sample evaluation are beyond the scope of this article and are given in the standards or other technical rules which are referenced.

3.2 Scanning Electron Microscopy

SEM, in combination with EDXA, enables the detection of fibers and the establishment of their elemental composition. Thus fibers may be classified, usually as chrysotile, amphibole asbestos, other inorganic fibers, or calcium sulfate fibers. This method is used to determine asbestos in air samples (ambient, indoor, and workplace air; section 3.2.1) and in bulk material samples (section 4.4).[1–4] Figure 1 shows a modern SEM set-up.

Figure 1 Modern SEM equipment. (Provided by R. König.)

Figure 2 Sampling apparatus with sampling head in two different working environments. (Provided by U. Teichert.)

3.2.1 Principle

A sample of airborne particulate is collected by drawing a measured volume of air through a gold-coated capillary-pore membrane filter (polycarbonate filter, diameter usually 25 mm) with a nominal pore size of 0.8 µm. Figure 2 shows an appropriate sampling apparatus in two different working environments.

The sampled volume depends on the objective of measurement. Usually it is 2 L min^{-1} per square centimeter of filter area over a period of 8 h. The dust-loaded filter is treated in a plasma asher (oxygen plasma) to remove organic particles that could interfere with the detection and analysis of the asbestos fibers.

Figure 3 shows a plasma asher, whereas Figure 4 shows a filter loading before and after plasma ashing treatment of a sample of airborne dust.

The filter is then examined in the SEM. The individual fibrous particles and constituent fibers in a randomly selected area of the filter (the total area of the randomly distributed image fields is 1 mm^2) are then counted at a defined magnification (for example 2000×) according to defined counting rules. The fiber is then examined at a higher magnification (for example 10 000×) to measure its dimensions and to determine its elemental composition using EDXA. The fiber data are recorded and the fiber classified accordingly.

Figure 3 Plasma asher.

Figures 5 and 6 show some examples of asbestos fibers on the filter surface, indicating the geometric dimensions and the corresponding EDXA spectra.

3.2.2 Characteristics

The range of concentrations for fibers greater than 5 µm in length and within the range of diameters that can be detected and measured under standard

Figure 4 Dust sample (a) before and (b) after plasma ashing treatment.

measurement conditions, is approximately 3–200 fibers per square millimeter of filter area. The air concentrations represented by these values are a function of the volume of air sampled.

The ability of the method to detect and classify fibers less than 0.2 µm in diameter is limited. If airborne fibers are predominantly less than 0.2 µm in diameter, a TEM method, such as ISO 10312,*(5) can be used to determine the smaller fibers.

The detection limit is defined as the fiber concentration below which, with 95% confidence (Poisson distribution), no fibers are found during the SEM examination. The detection limit can be lowered by filtration of progressively larger volumes of air and by examination of a larger area of the specimen in the SEM. In practice, the lowest achievable detection limit for a particular area of SEM specimen

Figure 5 Air samples drawn through gold-coated polycarbonate filters. The photographs show SEM images of very thin (a) crocidolite fibers, (b) chrysotile fibers (bent) and crocidolite fibers (straight), and (c) amosite fibers.

examined is controlled by the total suspended particulate concentration remaining after the plasma ashing step.

A detection limit of approximately 300 fibers per cubic meter is obtained if an air volume of 1 m^3 per square centimeter of filter surface area passes through the filter, and an area of 1 mm^2 of the filter area is examined

* Extracts from Clause 4 taken from ISO 10312: 1995, Clause 1 from ISO 13794 and Clause 2.5 from ISO/DIS 14966 have been reproduced with the permission of the ISO. in the SEM. This corresponds to an evaluated sample air volume of 0.01 m^3. Under these conditions a single detected fiber on the filter corresponds to 100 fibers per cubic meter.

This method had been developed and optimized as being cost-effective, economical to perform, and satisfying the needs of epidemiological research. The major goal concerning air quality characteristics was to provide a measurable result that reflects the concentration of airborne structures with the dimensions of the critical fiber (section 1).

3.3 Transmission Electron Microscopy

The TEM technique[5,6] is applicable to the determination of airborne asbestos in ambient and indoor air, and for detailed evaluation of any atmosphere in which asbestos structures are likely to be present.

TEM is currently the only technique capable of unequivocal identification of the majority of individual fibers of asbestos. However, it requires expensive and time-consuming measurement effort. Subjective and instrumental factors contribute to this measurement, and consequently a very precise definition is required of the procedure for identification and enumeration of asbestos. The sample preparation technique depends on the objective of measurement, i.e. whether the intention is to determine the concentration of airborne asbestos-containing structures or the asbestos fiber potential by disentangling the structures.

Airborne asbestos-containing structures comprise single fibers, fiber bundles, and even very complex and aggregated structures which may also be aggregated with other particles. The number of asbestos fibers and bundles incorporated in these complex structures can exceed the number of isolated fibers and bundles observed, and many of them may be completely obscured in *direct-transfer* sample preparations.[5] With the *indirect-transfer* preparation technique[6] organic and water-soluble materials are removed and the complex structures are dispersed via a liquid phase into their individual component fibers and bundles, hence giving a higher fiber count than direct transfer methods. However, the sample preparation effort is increased.

3.3.1 Direct-transfer Method

A sample of airborne particulate is collected by drawing a measured volume of air through either a capillary-pore polycarbonate membrane filter of maximum pore size of 0.4 μm or a cellulose-ester (either mixed esters of cellulose or cellulose nitrate) membrane filter of maximum pore size 0.45 μm by means of a pump. The choice of filter type determines the sampling pump required, as capillary-pore polycarbonate membrane filters produce a higher pressure drop than do cellulose-ester membrane filters.

TEM specimens are prepared from polycarbonate filters by applying a thin film of carbon to the filter surface by vacuum evaporation. Small areas are cut from the carbon-coated filter, supported on TEM specimen grids, and the filter medium is eliminated by a solvent extraction procedure (usually a Jaffe washer using chloroform (CAS 67-66-3) or *N*-methyl-2-pyrrolidone (CAS 872-50-4) as the solvent). This procedure leaves a thin film of carbon which bridges the openings in the TEM specimen grid, and which supports each particle from the original filter in its original position.

Cellulose ester filters are chemically treated (using a mixture of dimethylformamide (CAS 68-12-2), glacial acetic acid (CAS 64-19-7) and water) to collapse the pore structure of the filter. The surface of the collapsed filter is then etched in an oxygen plasma to ensure that all particles are exposed. A thin film of carbon is evaporated on to the filter surface and small areas are cut from the filter. These sections are supported on TEM specimen grids and the filter medium is dissolved away by a solvent extraction procedure (usually a Jaffe washer using dimethylformamide or acetone (CAS 67-64-1) as solvent).

The TEM specimen grids undergo a quantitative structure count on randomly selected grid openings (magnification 20 000×; lower magnifications can be used when larger objects, such as fibers longer than 5 μm, are to be determined). In the TEM analysis, ED is used to examine the crystal structure of a fiber, and its elemental composition is determined by EDXA. The analysis results are used to classify the fiber. The fiber classification procedure is based on successive inspection of the morphology, the ED pattern for a selected area, and the qualitative and quantitative EDXA. The identification of chrysotile is confirmed only by quantitative ED, and amphibole is confirmed only by quantitative EDXA and quantitative zone axis ED.

The lengths and widths of all classified structures are recorded. The number of asbestos structures found on a known area of the microscope sample, together with the equivalent volume of air filtered through this area, is used to calculate the airborne concentration in asbestos structures per liter of air.

3.3.2 Indirect-transfer Method

A sample of airborne particulate is collected by drawing a measured volume of air through either a capillary-pore polycarbonate membrane filter of maximum pore size 0.4 μm or a cellulose-ester (either mixed esters of cellulose or cellulose nitrate) membrane filter of maximum pore size 0.8 μm by means of a pump. The choice of the filter type determines the sampling pump required as capillary-pore polycarbonate membrane filters produce a higher pressure drop than do cellulose-ester membrane filters.

A portion of the filter is ashed in an oxygen plasma, and the residual ash is dispersed in distilled water with pH adjustment to between 3 and 4 using acetic acid. Analytical filters are then prepared by filtration of known volumes of this aqueous dispersion through either capillary-pore polycarbonate membrane filters of maximum pore size 0.2 μm or cellulose-ester membrane filters of maximum pore size 0.22 μm.

TEM specimens are prepared from polycarbonate analytical filters by applying a thin film of carbon to the filter surface by vacuum evaporation. Small areas are cut from the carbon-coated filter, supported on TEM specimen grids, and the filter medium is dissolved by a extraction procedure with an organic solvent (usually a Jaffe washer using chloroform or *N*-methyl-2-pyrrolidone as solvent). This procedure leaves a thin film of carbon which bridges the openings in the TEM specimen grid, and which supports each particle from the original filter in its original position.

Cellulose ester filters are chemically treated (using a mixture of dimethylformamide, glacial acetic acid, and water) to collapse the pore structure of the filter, and the surface of the collapsed filter is then etched in an oxygen plasma to ensure that all particles are exposed. A thin film of carbon is evaporated on to the filter surface and small areas are cut from the filter. These sections are supported on TEM specimen grids and the filter medium is dissolved away by a solvent extraction procedure (usually a Jaffe washer using dimethylformamide or acetone as solvent).

A quantitative fiber count on randomly selected grid openings is carried out at a magnification of approximately 20 000× (or less, depending on the fiber size/diameter spectrum to be analyzed). In TEM analysis, ED is used to examine the crystal structure of a fiber, and its elemental composition is determined by EDXA. The results are used to classify the fibers. The fiber classification procedure is based on successive inspection of the morphology, the selected area ED pattern, and qualitative and quantitative EDXA.

The lengths and widths of all classified structures are recorded. The number of asbestos structures found on a known area of the microscope sample, together with the volume of air filtered through the sample collection filter that was ashed, the proportion of the aqueous dispersion that was filtered, and the area of the analytical filter are used to calculate the airborne concentration of asbestos in asbestos structures per liter of air.

The examination consists of a count of the asbestos structures present on a specified number of grid openings. Fibers are classified into groups on the basis of morphological observations, ED patterns, and EDXA spectra. The total number of structures to be counted depends on the statistical precision desired. In the absence of asbestos structures, the area of the TEM specimen grids that must be examined depends on the analytical sensitivity required.

3.3.3 Characteristics

The upper limit for the range of concentrations that can be measured on the analytical filter is 7000 structures per square millimeter. The air concentrations represented by this value are a function of the volume of air sampled and the degree of dilution or concentration selected during the specimen preparation procedures. A minimum length of

0.5 μm has been proved to be a reasonable lower limit to the dimensions of asbestos fibers that should be recorded.

In theory the detection limit can be lowered indefinitely by filtration of progressively larger volumes of air, concentrating the sample during specimen preparation (indirect-transfer method), and by extending the area to be examined. In practice, the lowest achievable detection limit for a particular area of TEM specimen examined is controlled by the total suspended particulate concentration remaining after ashing and aqueous dispersal steps. In order to achieve lower detection limits for critical fibers (section 1), lower magnifications permit more rapid examinations of larger areas of the TEM specimens when the examination is limited to these dimensions of fiber.

3.4 Phase Contrast Optical Microscopy

The PCOM method,[7–9] despite its limitations concerning visibility and identification, is well-proven for widespread international use in the field of occupational hygiene and measurement of asbestos emissions from stationary sources.

*3.4.1 Principle**

A sample is collected by drawing a known volume of air through a membrane filter (membrane of mixed esters or cellulose nitrate, 0.8–1.2 μm pore size) by means of a pump. The filter is exposed to acetone vapor, which condenses on the filter, collapsing its pores and making it transparent. Different methods are described for this procedure.[7–9] The filter is then fixed to a glass slide, where it appears as a transparent and uniform plastic film with any fibers on the upper surface. A liquid must be added to provide optimal contrast – if the refractive index of the fibers exceeds 1.51 then triacetin (glycerol triacetate, CAS 102-76-1) is satisfactory; for inorganic fibers with refractive indices less than 1.51 the filter surface must be etched to expose the fibers using a plasma asher. Distilled water is then used as the contrast liquid. Fibers on a measured area of the filter are counted visually using PCOM with a magnification of 400–600, and the concentration of fibers in the volume of air sampled is calculated.

*3.4.2 Characteristics**

This method is usually used to measure the fiber concentration of airborne structures present with the critical dimensions length greater than 5 μm, diameter less than 3 μm, and aspect ratio greater than 3:1. The minimum visible width depends on the resolving power of the optical system, the difference in refractive index between the fiber and the contrast liquid and – as for all fiber counting methods – the visual acuity of the microscopist. Thus the limit of visibility can be as low as about 0.15 μm, but is usually higher in practice. The detection limit depends on the extent of sampling and evaluation, and especially the blank value of the analytical filters. The practical limit is 10 000 fibers per square meter or higher.

The method does not permit the determination of the chemical composition or crystallographic structure of fibers, and therefore cannot be used to discriminate between different fiber types. Supplementary information on fiber type may be obtained by using other methods, such as PLM, SEM, or TEM.

4 DETERMINATION OF ASBESTOS IN BULK MATERIALS

4.1 General

The comprehensive use of asbestos in the past has produced the present-day need to identify and possibly quantify asbestos in a variety of asbestos-containing industrial products. These include building materials such as loose-fill insulation, pipe and boiler wraps, plasters, paints, flooring products, roofing materials, and cementitious products. The diversity of these bulk materials necessitates the use of several different methods of sample preparation and analysis.[10] Figure 7 shows SEM images of different asbestos-containing products.

A precondition for a reliable analytical result is a representative sample of the materials of interest.[11] Many manufactured products containing asbestos, such as boards, sheets, cement pipes, textiles, ropes, friction products, plastics, and vinyls can be assumed to have the asbestos uniformly distributed throughout the material. Thus, a relatively small sample can be taken as being representative of the whole. Other products may be layered and the asbestos will be present in part of the cross-section. Insulation and spray materials tend to be more variable. Insulation was often wet-mixed on-site and subsequent repairs and patching may add to this variability. Samples should be taken that are representative of the whole material.

The sample may require mechanical and/or chemical treatment in order to release fibers from any matrix and to remove adhering particles prior to fiber analysis (microscopic methods). Any preparation technique must preserve the integrity of morphology, structure, and chemistry of the fibrous particles. IR and XRD require careful homogenization of the sample.

The simplest analytical method is the use of a stereomicroscope which provides preliminary information on the sample and the fiber type. Stereomicroscopic analysis

* Reproduced by permission of WHO.

Figure 7 SEM images of different asbestos-containing products: (a) sprayed-on insulation material, (b) asbestos cement, (c) floor covering (vinyl floor tile).

determines the homogeneity, texture, friability, color, and the extent of fibrous components of the sample. This information is then used as a guide to the selection of further, more definitive qualitative and quantitative asbestos analysis methods.

Qualitative and semiquantitative results may be obtained by additional analyses, such as PLM,[10,11] XRD,[10] analytical electron microscopy (AEM),[10] or IR spectroscopy.[12,13]

The accuracy, precision, and detection limits of the different analytical techniques for bulk material analysis are dependent on the type of sample (matrix, components, texture, etc.), the preparation of the sample (homogeneity, grain size, etc.), and the specifics of the method.

4.2 Polarized Light Microscopy

Samples are examined using PLM to determine optical properties of constituents and to provide positive identification of suspect fibers. The major goal of the qualitative preparation is to mount easily visible representative fibers or fiber bundles in appropriate refractive index liquids on microscope slides for complete optical characterization. A tentative identification based on the stereomicroscopy evaluation or other preinformation is used to select the most appropriate mounting liquid. Identification of a single asbestos fiber as one of the six regulated asbestos types requires assessment of the following optical properties using PLM with magnifications from about 80 upwards, as appropriate:

- morphology
- color and pleochroism (if present)
- birefringence
- extinction characteristics
- sign of elongation
- refractive index assessment.

Identification is based on comparing the recorded observations (morphology, optical properties) on the analyzed fibers against the properties of asbestos reference standards. A close match between the optical properties of the sample fiber and the asbestos standard will normally be achieved.

Figures 8–10 show the application of PLM to asbestos identification. The semiquantitative estimation of the asbestos content in a sample is possible.[10]

4.3 X-ray Diffraction

In powder XRD analysis, a bulk sample of material is subjected to X-ray radiation and the angle of the diffracted radiation is measured. The solid powdered crystalline sample will diffract the incident beam of parallel, monochromatic X-rays whenever Bragg's law is satisfied for a particular set of planes in the crystal lattice. A diffraction pattern is generated which is a characteristic of the structure of the crystalline phases present.

This technique allows determination of the crystal structure of mineral compounds. However, XRD cannot determine crystal morphology. Therefore in asbestos

Figure 8 Chrysotile fiber bundles in cinnamic acid ethyl ester; positive phase contrast; fibers parallel to polarizer are blue with orange-red halo.

Figure 9 Chrysotile fiber bundles and MMMF (thick bent object) in cinnamic acid ethyl ester; positive phase contrast; fibers parallel to polarizer are blue with orange-red halo; the MMMF shows no optical effects.

analysis, it is not possible to distinguish between fibrous and nonfibrous forms of serpentine and amphibole minerals using XRD. XRD should be used in conjunction with other methods, such as PLM or electron microscopy, and thus can provide a reliable analytical method for the identification (diffraction pattern), characterization, and quantitation (signal intensities) of asbestiform minerals in bulk materials. In order to identify the minerals the diffraction patterns should be compared with powder diffraction patterns of well-characterized reference materials.

Quantitative results require calibration. Accurate quantitative analysis of asbestos in bulk samples by XRD is critically dependent on particle size distribution, crystallite size, preferred orientation and

(a)

(b)

Figure 10 Birefringence: (a) chrysotile fibers are clearly visible between crossed polars, whereas the isotropic MMMF is not visible; (b) with the first-order red compensator the chrysotile fibers appear blue or yellow, depending on their orientation with respect to the polarizer, and the MMMF is visible.

matrix absorption effects, and comparability of standard reference and sample materials.[10]

Figure 11 shows the XRD spectra of the six different asbestos types. The samples were prepared for routine qualitative analysis.

4.4 Analytical Electron Microscopy

Both SEM[14] and TEM[10] can be used to examine bulk material samples, the latter being more expensive and time-consuming.

The preliminary visual inspection and examination of the material using the stereomicroscope served to identify representative or relevant portions which are prepared as samples for SEM. SEM allows a direct investigation of the surface of the sample, even if the surface is highly structured. The sample is mounted on

Figure 11 XRD spectra of the six asbestos types: (a) chrysotile 7 M 4 (Canada), (b) crocidolite KCBR (South Africa), (c) amosite S 11 (South Africa), (d) anthophyllite (International Union Against Cancer (UICC) reference standard), (e) actinolite, and (f) tremolite (Institute of Occupational Medicine (IOM) reference standard).

the sample holder or sputtered with carbon or gold. The sample is examined with respect to asbestos fibers initially with low (20–50), then with high (500–2000) magnification. Negative results have to be verified with a magnification of 5000–10 000. Detected fibers are assessed morphologically, and the elemental composition is determined using EDXA. Based on these analytical results the fibers are classified or even identified. SEM is very useful for observing surface features in complex particles, and for determining elemental compositions.

The application of TEM to bulk material analysis has been described in detail.[10] The sample material is treated by ashing or dissolution or, when this is not possible, at least by grinding or milling. The material is then dispersed in an organic solvent. A small volume of this suspension is transferred to the top of a carbon-coated TEM grid, the solvent is evaporated, and the grid examined for qualitative and semiquantitative analysis. Quantitative evaluation requires some additional procedural steps. A known weight of the bulk sample, after preparation, is dispersed in distilled water, filtered (see section 5) and TEM grids are prepared from appropriately loaded filters using the standard methods.

4.5 Infrared Absorption

This technique indicates the possible presence of certain functional groups in the components analyzed but cannot distinguish between fibers and other material with the same chemical properties. The resonant absorption of IR radiation is measured for peaks indicative of various functional groups.

Chrysotile shows a characteristic double band in the near IR at about 3660 and 3700 cm^{-1} (−OH stretching vibrations). The intensity of the latter is used for quantitation.

The IR spectra of the amphibole asbestos types are quite similar. A group of characteristic bands is found in the mid- and far IR in the wavenumber range between 300 and 1200 cm^{-1}. The absorption band at 780 cm^{-1} has proved best for the quantitation of crocidolite and amosite. Figure 12 shows the IR spectra of chrysotile, crocidolite, and amosite. The IR method is proven only for these three asbestos types.

Figure 12 IR spectra of (a) chrysotile, (b) crocidolite, and (c) amosite.

Solid samples are prepared as follows. The powdered sample is homogeneously mixed with potassium bromide (CAS 7758-02-3) and pressed to form a transparent pellet. The IR spectrum of the sample is recorded in the range between about 250 and 4000 cm^{-1}.

As IR spectra do not contain any information about morphological structures, it is useful to verify the presence of fibrous structures using a light microscope, if IR indicates the presence of asbestos – especially amphibole – so as to avoid false positive identification as far as possible.

5 DETERMINATION OF ASBESTOS FIBERS IN DRINKING WATER

Asbestos cement pipes, used within drinking water supply networks, also need to be considered critically. Fiber release from this type of pipe depends on the condition of the material matrix and surface and also on the characteristics of the water, especially its saturation index. When the water is around saturation with respect to calcium carbonate, the fiber release tends to a minimum.

Due to the variety of fibrous particles in water, a method is required that allows identification of the fiber type and the visibility of fibrils at least 0.5 μm in length. Thus TEM, including EDXA and SAED, is the preferred method[15] (section 3.3). SAED allows the identification of particles of organic origin that cannot be ashed, such as specific parts of diatoms or excretions of iron-accumulating microorganisms. The recommended characteristics are:

- membrane filter pore size 0.2 μm;
- magnification 10 000;
- analytical sensitivity 3300 fibers per liter (corresponding to one detected fiber);
- detection limit 10 000 fibers per liter.

Health risks as a result of oral uptake of asbestos fibers from drinking water are not evident so far. Consequently WHO does not recommend a limiting value for asbestos fibers in drinking water.

6 QUALITY ASSURANCE

Usual and adequate intralaboratory quality assurance measures with respect to qualified personnel, laboratory equipment, reference material, etc. can be based on the standard EN 45001 or the draft standard ISO/IEC

DIS 17025.[16,17] In addition, an essential part of quality assurance for fiber-counting methods is the performance of counting checks because of the large differences in results obtained within and between laboratories using microscopical counting. In practice, the effects of chance superimposition on counting results are small compared with effects due to differences between individual microscopists. Laboratories using fiber-counting methods should participate in a national or international proficiency testing scheme in order to minimize interlaboratory variation. Interlaboratory exchange and verification of samples can further complement internal quality control.

The purpose of the quality assurance program is to minimize failures in the analysis of materials prior to submitting the results to the client. Failures in the analysis of asbestos materials include false positives, false negatives, and misidentification of asbestos types. False positives result from identification or quantitation errors. False negatives result from identification, detection, or quantitation errors.

Atomic fluorescence is a spectroscopic process which is based upon the absorption of radiation of a certain wavelength by an atomic vapor and subsequent radiational deactivation of the excited atoms toward the detection device. Both the absorption and the subsequent atomic emission processes occur at wavelengths which are characteristic of the atomic species present. Atomic fluorescence spectroscopy (AFS) is a very sensitive and selective method for the determination of a number of environmentally and biomedically important elements such as mercury, arsenic, selenium, bismuth, antimony, tellurium, lead, and cadmium. This technique has become one of the most important analytical tools for trace element analysis in environmental samples, such as mercury, owing to its advantages over other methods in terms of linearity and detection levels. Several books and a number of book chapters and review articles have been published dealing with the theory and instrumentation of AFS. This article will provide up-to-date AFS information regarding its application in environmental analysis.

R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

1 THEORETICAL ASPECTS

1.1 Types of Atomic Fluorescence

The main types of atomic fluorescence process are illustrated in Figure 1(a–c), which shows diagrammatically the transitions involved. *Resonance fluorescence* occurs when atoms absorb and re-emit radiation of the same wavelength (Figure 1a). Many of the measurements made by analytical chemists employing AFS involve this type of fluorescence. The most analytically useful fluorescence line is the resonance fluorescence corresponding to the transition between an electronic excited state and the ground state of the atom.[1] The wavelengths of the absorption (λ_A) and fluorescence (λ_F) can also be different. If the photon energy of fluorescence is less than the photon energy of absorption, i.e. $\lambda_F > \lambda_A$, the process is called Stokes-type fluorescence. If the reverse is true, i.e. $\lambda_F < \lambda_A$, this process is called anti-Stokes type fluorescence.[1–3] *Direct line fluorescence* is nonresonance fluorescence, which is observed when a common upper level is involved for both excitation and fluorescence. Figure 1(b) shows an example of direct line fluorescence in which an atom is excited from the ground state to a higher excited electronic state and then undergoes a direct radiational transition to a metastable level above the ground state. *Stepwise line fluorescence* (Figure 1c) occurs when the upper energy levels of the exciting and of the fluorescence line are different. The excited atoms may undergo deactivation, usually by collision, to a lower excited state rather than return directly to the ground state. There are several more fluorescence lines which are not of much analytical use. Details about those fluorescence lines can be found in the literature.[1–6]

Generally, an atomic fluorescence spectrum consists of only a few lines because not all of these fluorescence-generating processes are active simultaneously.[7] Therefore, the atomic fluorescence spectrum is much simpler than the one obtained using atomic emission spectroscopy (AES).

1.2 Intensity of Fluorescence Radiance

It is beyond the scope of this article to provide details about the derivations of the intensity expressions. Only the results of the derivations will be given in order to understand the various dependences of the fluorescence signal. For a more comprehensive discussion and a complete derivation of the expressions, articles by Winefordner et al.[4,6,8] can be highly recommended.

The intensity of the fluorescence radiation produced in a transition depends on a number of factors, the most important of which are[5,7] (a) the intensity of the excitation source, (b) the concentration of the atom in

Figure 1 Basic types of atomic fluorescence lines.

the atomizer, (c) the quantum efficiency of the process (i.e. the ratio of the energy emitted in fluorescence to the energy absorbed, per unit of time), and (d) the extent of self-absorption in the atomizer.

In the derivation of intensity expression, it has been assumed that the atom under consideration has only two energy levels, ground state (1) and first excited state (2).[4] Other important assumptions are that the atoms are uniformly distributed in the atomizer and the concentration of the analyte atom is low, and the temperature of the atomizer and the radiation density of the source are spatially uniform. The fluorescence radiance[4,5,7] can be given by Equation (1):

$$B_F = \left(\frac{l}{4\pi}\right) Y_{21} E_{\nu_{12}} \int_0^\infty k_\nu \, d\nu \qquad (1)$$

where B_F is the absolute radiance; l is the pathlength in the direction of the detector; Y_{21} is the fluorescence power efficiency, $W_{\text{fluoresced}}/W_{\text{absorbed}}$; $E_{\nu_{12}}$ is the spectral irradiation of source at absorption line of frequency ν_{12}; and k_ν is the absorption coefficient.

The integration term gives the integrated absorption coefficient over the absorption line, which is a function of the concentration in states (1) and (2), the statistical weights of state (1) and state (2), and the Einstein B_{12} absorption coefficient.

The above equation gives some analytically important information. The fluorescence radiance B_F is linearly dependent on the source irradiance and the fluorescence quantum efficiency of the transition as long as $E_{\nu_{12}}$ is very much below the saturation value. Therefore, in order to obtain a large fluorescence signal it is necessary to use a highly irradiant light source. It can be further demonstrated that if the atomic concentration is low, B_F is linearly related to the total concentration of atoms in all states.[3]

1.3 Quenching

The intensity of the atomic fluorescence can be diminished by the collision between excited atoms and other molecules in the atomization sources. This process is called quenching. This problem is accounted for by the inclusion of the term Y_{21} in the fluorescence radiance equation given above. Since the quenching process is very important in atomic fluorescence, a few examples are given below. For a more comprehensive discussion on quenching processes, the reader is referred to several good reviews.[2,9]

1. The excess electronic energy of the excited atoms is converted into translational energy of the colliding species without involving the internal energy of the latter. For instance, this quenching can be processed by collision with free atoms (Equation 2):

$$A^* + B \longrightarrow A + B \qquad (2)$$

or with free electrons (Equation 3):

$$A^* + e^- \longrightarrow A + e^- \qquad (3)$$

2. The excess electronic energy of the excited atoms is released on collision, resulting in changes of the electronic or vibrational/rotational energy of the colliding species, for instance quenching by collision

with other atoms (Equation 4):

$$A^* + B \longrightarrow A + B^* \quad (4)$$

or with molecules (Equation 5):

$$A^* + BC \longrightarrow A + BC^* \quad (5)$$

Depending on the experimental conditions used, some of these quenching processes can significantly affect the fluorescence radiance.

1.4 Interferences

As with atomic absorption spectroscopy (AAS) and AES methods, interferences of two major types are encountered in atomic fluorescence.[10] Spectral interferences arise when lines in the source overlap lines of the matrix elements in the atomizer. Chemical interferences result from various chemical processes during atomization that reduce the population of free atoms.

Spectral interferences are seldom caused by line sources, but may be a problem with nondispersive instruments or in dispersive apparatus with continuum sources. Since generally there are several fluorescence lines available, it is sometimes necessary to select different lines to avoid the spectral interference. Chemical interferences caused by matrix components are one of the major problems in atomic fluorescence. This type of interference can be reduced by introducing different chemicals into the matrix, such as releasing agents and protective agents.[10] Coupling to vapor generation can also significantly reduce the problem.

2 INSTRUMENTATION

The basic layout of an AFS instrument is similar to those for AAS and AES except that the light source and the detector are located at a right-angle. A schematic diagram of an AFS instrument is shown in Figure 2. Although the configuration of an AFS instrument can be modified for different purposes, the basic apparatus consists of a radiation source, an atomizer, a wavelength-selection system, a signal detector, and an electronic readout system.

Figure 2 Schematic diagram of an AFS instrument.

2.1 Excitation Sources

A number of excitation sources have been used in AFS and can be categorized into two types, spectral line sources and continuum sources. Since the intensity of the fluorescence radiance is proportional to the intensity of the exciting radiation, sources with high radiance are required in order to achieve a good sensitivity and linear range. Indeed, a major part of the effort devoted to improvement of AFS instrumentation in recent years has been concerned with the excitation source. Winefordner discussed the criteria of importance in choosing excitation source for AFS and provided some general considerations.[3,4] Briefly, in addition to a high radiance over the absorption line (in order to obtain a good detection limit (DL) and linear range), the source should have good short- and long-term stability. In view of the need for convenience and ease of use, the source used should also require a minimum of maintenance and adjustment to obtain optimum performance. Only the most commonly used and recently developed sources are discussed here.

2.1.1 Hollow-cathode Lamps

Although the conventional, and commercially available, hollow-cathode lamp (HCL) is the most widely used line source used in AAS,[2,5] the early version of the HCL did not show impressive potential as a useful radiation source for AFS because it does not possess sufficient intensity. Different efforts have been made to improve the design of HCLs.[1,2,5,11,12] For instance, the lamps can be operated using short-duration pulses of current with a sufficient off-period between pulses to maintain the mean lamp current at a low level. The pulsed lamps provide an increase in peak intensity and a reduction of the total signal observation time.[1] Compared with regular HCLs, good results have been obtained with pulsed HCLs for a large number of elements.[1,5,13]

The boosted discharge hollow-cathode lamp (BDHCL), or boosted output HCL as it is sometimes called, produces intense spectra with narrow line widths and can be manufactured to provide an excellent source for many elements.[1,5,14] Since its introduction as an AFS excitation source by Sullivan and Walsh,[15] it has received a great deal of attention and a number of modifications to this type of source have been made.[1,11,16] Recently, BDHCLs have become commercially available and this contributed significantly to the availability of commercial AFS instruments.[12]

The operation principle of the BDHCL is illustrated in Figure 3.[14] The lamp consists of an anode mounted behind a cylindrical cathode. A primary discharge is struck between the cathode and anode to sputter atoms of the element of interest, as in a normal

Figure 3 Schematic diagram of the boosted discharge HCL lamp. (Reproduced from *PSA 10.055 Millennium Excalibur, User Manual*, Issue 1.0, March 1998, by permission of P. S. Analytical.)

HCL. However, a secondary discharge (boost) is then struck between an efficient electron emitter and the anode, passing through the primary atom cloud. The use of a specifically developed high-efficiency electron emitter permits operation of the secondary discharge so that concentration broadening and line broadening are minimized.

2.1.2 Electrodeless Discharge Lamps

Electrodeless discharge lamps (EDL) are useful sources of atomic line spectra and provide radiant intensities that are usually one or two orders of magnitude greater than the normal HCLs.[10] This type of lamp has been widely employed for AFS. A typical lamp is constructed from a sealed quartz tube containing a few torr of an inert gas such as argon and a small quantity of the metal of interest (or its salt). The lamp does not contain an electrode but instead is energized by an intense field of radio frequency or microwave radiation. Radio and microwave frequency electromagnetic fields are very efficient for generating and accelerating electrons and thereby maintaining a gaseous glow discharge without internal electrode contact with the plasma.

The characteristics of EDLs have been studied and discussed in some detail.[5,17] Useful recommendations have been given by Van Loon[5] to predict lamp behavior and to select operating conditions for the EDLs for AFS. The main drawbacks of the EDLs are that their performance does not appear to be as reliable as that of the HCLs (signal instability with time) and they are commercially available only for some elements.

2.1.3 Xenon Arc Lamps

High-pressure xenon arc lamps, producing a stable and intense continuum source, have been commercially available for many years.[1,5] The lamp produces intense radiation by the passage of current through an atmosphere of xenon. The spectrum is continuous over the range 250–600 nm, with the peak intensity about 500 nm.[10] The advantage of this type of continuum source is that it can be readily employed for multielement analysis along with the use of a monochromator or interference filters. However, its intensity falls off severely below about 210 nm, thus making it unsatisfactory for the analysis of some environmentally important elements such as arsenic and selenium.

2.1.4 Laser Sources

Lasers have become important sources in analytical instrumentation because of their high intensity and narrow bandwidths and the coherent nature of their outputs. As a consequence of these unique properties, laser-induced fluorescence (LIF) offers a very sensitive and selective spectroscopic method, which has a low susceptibility to spectral interferences. Compared with conventional light sources, laser excitation also allows nonresonance transition lines to be used for many elements, which significantly reduces any laser radiation scattered off the vaporized sample.

LIF has been used for the determination of many elements in a variety of samples,[18–23] including environmental matrices.[21,24,25] The most sensitive DLs that have been reported have been as low as a few attograms.[21,26] The basic requirements for the laser include wavelength tunability across the ultraviolet (UV) and visible spectrum to allow for the determination of as many elements as possible. The most commonly used LIF is the pulsed excimer- or yttrium aluminum garnet (YAG)-pumped tunable dye laser because it provides sufficient peak energy and wavelength tunability. However, this type of source has some drawbacks, such as the need to replace the dry solution, which is often toxic and flammable, before a wavelength change of more than 20–30 nm, and dye degradation with time.[21] These disadvantages have significantly limited the application of this type of laser source to routine sequential multielement analysis. Research has been conducted to find alternatives to the pulsed dye laser. Recently, Zhou et al.[21] reported a pulsed (10 Hz) optical parametric oscillator (OPO) laser system based on β-barium borate crystals and equipped with a frequency-doubling option for use in LIF. This all-solid-state laser has a narrow spectral line width and wide spectral tuning range (220–2200 nm). It has been used for cobalt, copper, lead, manganese, and thallium analysis in Buffalo River sediment samples.

The production of far-UV radiation is required for excitation of some elements, such as arsenic at 193.70 nm and selenium at 196.03 nm. With the availability of β-barium

borate crystals, tunable UV radiation is now generated at wavelengths down to 205 nm by frequency-doubling. Sum frequency generation or stimulated Raman shifting techniques can further extend the UV range down to 187 nm with reasonable efficiency, making the determination of metalloids feasible.[22] Recently, Swart et al.[22] reported an LIF technique for selenium, arsenic, and antimony analysis. The far-UV radiation required was accomplished by stimulated Raman shifting of the output of a frequency-doubled dye laser operating near 230 nm.

2.1.5 Mercury Arc Lamps

The mercury arc lamp is a type of vapor-discharge lamp that forms simple, robust sources of line spectra.[10] The low-pressure mercury-vapor lamp equipped with a fused-silica window has been the most common source for filter fluorometers. This source produces intense lines at 254, 366, 405, 546, 577, 691, and 773 nm. Individual lines can be isolated with suitable absorption or interference filters. The mercury lamp has been used in commercially available instruments with a 254-nm filter for mercury analysis.[27]

2.2 Atomizers

Many atomizers used for AFS are similar to those used for AAS and AES. The design and properties of these atomizers have been discussed comprehensively in terms of their applications for AFS.[1–3,7] The basic requirements of an atomizer for AFS are an efficient and rapid production of free atoms with minimum background noise, long residence time of the analyte atoms in the optical path, low quenching properties, low cost of operation, and ease of handling. The quenching process is especially important for AFS and has been taken into consideration in the design of the atomizer. The order of quenching efficiency for some gases is $Ar < H_2 < H_2O < N_2 < CO < O_2 < CO_2$.[28] A number of atomizers have been developed and used for AFS, and some improvements have been made in recent years.

2.2.1 Flame Atomizers

Perhaps the most commonly used flame atomizer[5,7] in early studies was a premixed laminar flame with inert gas sheaths. Without using inert gas sheaths, the premixed laminar flame, in particular the acetylene-based flame, exhibits high background emission due to radicals present in the secondary reaction zone (OH, C_2, CH, CN) resulting in poor DLs. By preventing entrainment of the surrounding atmosphere into the flame gases, the secondary reaction zone may be shifted away from the primary reaction zone, thus extending the region of interconal zone, which is the most used part of the flame for spectroscopy. Separation of the secondary reaction zone can be effected using either nitrogen or argon. Argon is favored over nitrogen because of its greatly reduced quenching cross-section.

Flame emission and the associated flame flicker noise considerably increase the limits of detection in AFS. Flames with low background emission are therefore necessary. Diffusion flames, sometimes called cool flames, were developed and used for this purpose. The term diffusion flame is generally applied to flames in which the oxidant necessary for combustion is fully supplied by diffusion and/or entrainment from the surrounding atmosphere.[1] Argon is generally used as carrier gas and hydrogen is used as fuel gas. The temperature of these argon–hydrogen–air flames ranges from 280 to 850 °C, depending on the flame region selected. Despite the relatively low temperature achieved by these flames, they are still widely used as efficient atomizers for the analysis of some environmentally important elements. Indeed, a very simple atomizer based on an argon–hydrogen diffusion flame has recently been employed in a commercially available AFS system for hydride-forming elemental analysis.[12] The argon–hydrogen diffusion flame used emits very low background radiation over the wavelength region of interest, and the hydride compounds are easily decomposed in such a low-temperature flame. In addition, the quenching effect is relatively low in the argon-supported flame and in hydrogen.

Different designs of diffusion flame atomizers have been proposed and studied.[12,29–32] A simple glass or silica tube (i.d. 4–8 mm) has been used to support the argon–hydrogen flame.[31] Corns et al. recently investigated four different types of diffusion flame atomizers for arsenic analysis using hydride-generation/atomic fluorescence spectroscopy (HG/AFS) technique.[12] From this comprehensive study, they concluded that the AFS signals were observed only in the presence of argon–hydrogen flames. The attempt to achieve atomization using an electrically heated atomizer alone, without an argon–hydrogen diffusion flame, failed. These results provided further evidence to support the atomization mechanism proposed by several workers.[1,33–36] The atomization at such low temperature (about 800 °C) is not due to thermal decomposition, but to free radicals in the flame.

2.2.2 Electrothermal Atomizers

Although the flames discussed above are very convenient and have been widely used as atomization cells in AFS, they do have disadvantages for some analytical work. The high dilution of the sample by flame gases limits the atom concentration attainable. The large sample requirement with continuous nebulization makes

it unsuitable for small-volume sample analysis, and the flame cells are not convenient for the direct atomization of solid samples. Precise control over the chemical environment in the flame is impossible. These drawbacks of the flame atomizer can be overcome by using electrothermal atomization (ETA) techniques. These electrothermal atomizers are designed in different shapes and are generally made of graphite. Graphite atomizers are operated at high temperature and the atoms are contained in an inert gas atmosphere. This provides a high atomization efficiency and reduced quenching, consequently offering high sensitivity for small volumes of sample. It has been suggested that the most successful atomic atomizer for LIF spectrometry is the graphite furnace.[19]

LIF coupled with ETA has been one of the main research fields for many scientists in the past two decades.[19,20,22–24,37–40] The development of electrothermal atomizers used for AFS benefits greatly from the analytical knowledge accumulated over the years with the well-established atomic absorption technique. Generally, certain modifications of the conventional graphite furnaces are required if they are to be usable in LIF. The optical detection of fluorescence needs to be made at 90° with respect to the excitation axis. The following are the typical forms of the graphite furnace studied for AFS: graphite cup,[37] Massmann cup,[41] graphite rod,[42,43] and graphite tubes.[38,39] There seems to be a general consensus that graphite-tube atomization is preferable to other graphite atomization techniques,[39] and it has been used in most of the later studies.[19,20,22] With graphite-tube atomization, the atoms are contained in a hot environment while being excited by the laser, and therefore much better analytical performance can be achieved.

Besides examining a variety of designs and shapes for the furnace, other studies, such as those atomizing at a pressure-controlled[20] and pyrolytically coated[44] graphite atomizer, have also been conducted to improve the performance of these furnaces. The use of low-pressure vaporization to remove matrix interferences associated with the analysis of solid samples has been coupled with laser-induced fluorescence/electrothermal atomization (LIF/ETA).[45] A lower DL was found by using the low-pressure vaporization technique. Using a coating on graphite furnaces was initially conducted in ETA in the AAS technique to inhibit reaction between the analyte and the graphite.[46] Among the different coating methods used for the graphite atomizer in AFS, a pyrolytic coating has been the most popular.[19,20,38]

2.2.3 Cold-vapor Technique for Mercury

Mercury is the only metallic element that exhibits an appreciable atomic vapor pressure at ambient temperature. The mercury has a vapor pressure of 0.0016 mbar ($1\,\text{mbar} = 10^2\,\text{Pa}$) at 20 °C, corresponding to a concentration of approximately $14\,\text{mg}\,\text{m}^{-3}$ in air.[46] This unique property gives rise to the possibility of measuring mercury without the additional thermal energy supplied by a flame or electrothermal heating. The cold-vapor atomic absorption spectrometry (CVAAS) technique for mercury analysis has been studied extensively. This method is readily applicable to AFS [cold-vapor atomic fluorescence spectrometry (CVAFS)]. Briefly, the mercury vapor, produced by reduction of the metal from its compounds with suitable reductants [sodium borohydride or tin(II) chloride], is swept out of the reaction vessel using argon carrier gas and introduced into the optical beam where the mercury atoms can be excited with a suitable source.

2.2.4 Miscellaneous Atomization Techniques

The inductively coupled plasma (ICP) has been proposed as an atomizer for AFS.[47,48] Plasmas have better vaporization and atomization efficiency than flames and give less interference problems. Within an argon atmosphere, ICP is characterized by a high fluorescence yield because of the small quenching cross-section. Background emission is dependent on the viewing region but is generally higher than in flame.[28] Although the ICP shows some advantages as an atomizer, the high cost compared with flame and electrothermal atomizers has discouraged its widespread application to routine AFS.

The atomization of an analyte can be also carried out on the principle of an HCL in which the sample is vaporized by a glow discharge.[46] Recently, a microsecond pulsed glow discharge was studied as an analytical spectroscopic source for solid-sample analysis.[49] The results showed enhanced efficiency for analytical response of the sputtered sample atoms.

2.3 Wavelength Selection and Detection Systems

The simplicity of atomic fluorescence spectra makes the isolation and detection of the selected atomic fluorescence lines easier than in other atomic spectrometric techniques such as AAS and AES. Both a monochromator and an interference filter have been used as wavelength selectors with different advantages and limitations. The requirements for wavelength selection depend on the light source employed. With conventional line sources (HCL, EDL) or laser excitation, low-dispersion monochromators or nondispersive systems can be used. The nondispersive instruments are simple and cheap, and readily adaptable to multielemental analysis. They also have a high energy throughput and thus high sensitivity.[10] However, to realize these advantages, it is necessary that the output of the source is free of contaminating lines from other elements, and no significant background radiation should occur. In most of the instruments, a filter located between

the source and detector has been used to remove background radiation. With a continuum excitation source, a dispersive system is required to discriminate against the scattering of source radiation and the fluorescence radiation from other species over the entire ultraviolet/visible (UV/VIS) region.[28]

Fluorescence radiation is usually detected with a photomultiplier tube (PMT) as in many other spectrometers.[7,10] The PMTs are highly sensitive to UV and visible radiation and have extremely fast response times.

Since the wavelength selection and detection systems used in AFS are similar to those of AAS and AES, readers are referred to other comprehensive discussions in the literature.[10,46] Over the years, a number of AFS instruments have been developed, and have either been used exclusively in research laboratories or have only recently become commercially available. To the author's knowledge, AFS instruments for the analysis of mercury and some other elements are currently being manufactured by three companies: P. S. Analytical Ltd, Sevenoaks, Kent, UK, Brooks Rand Ltd, Seattle, WA, USA, and Tekran Inc., Ontario, Canada. Different features of these instruments will be discussed in the following sections along with their applications in environmental analysis.

3 ENVIRONMENTAL APPLICATIONS

3.1 Mercury

Mercury pollution has become a global problem because of its wide occurrence in the environment. The toxicological effects of mercury compounds on environmental systems have long been recognized. Therefore, mercury monitoring is a special concern in the field of heavy metal analysis. AFS-based techniques have been widely used in environmental analysis. The resonance fluorescence line at 253.7 nm ($^3P_1 - {}^1S_0$ transition) has been generally used in most atomic fluorescence studies on mercury. AFS instruments are now commercially available for both total mercury and organomercury species analysis.

3.1.1 Total Mercury

3.1.1.1 Instrumentation Traditionally, CVAAS has been the most commonly used method for determining mercury at trace levels. This technique has been well established and several commercial systems are available.[46] CVAFS was proposed almost three decades ago as a method for mercury analysis.[50–52] The advantages of AFS over AAS, in terms of sensitivity, linear range, and spectral interferences, have been demonstrated both theoretically[53] and experimentally.[50,54] However, it was only during the beginning of the 1990s that AFS became commercially available.[55,56] AFS detection, especially coupled with the vapor generation technique, is becoming popular and replacing AAS for mercury analysis in many research and service laboratories owing to its unique sensitivity, specificity, and simplicity.

Similarly to CVAAS, a general CVAFS system consists mainly of two parts, the mercury vapor generator and the AFS detector. A schematic diagram of a continuous-flow vapor generator is shown in Figure 4.[27] The reductant, blank (1% HCl), and sample solutions are delivered by variable-speed multichannel peristaltic pumps. An electronically controlled switching valve alternates between blank and sample solutions, and two of the liquid streams (reductant and sample or reductant and blank) are butt-mixed in the sample valve, where the reaction starts to occur. The steams and all gaseous products are continuously and rapidly pumped into a glass gas–liquid separator, from which the gaseous products are carried, by argon gas, through a dryer system, finally reaching the AFS detector.

The design of the AFS detector for mercury analysis is relatively simple owing to the absence of a thermally energized atomizer.[55,57] Generally, a UV mercury vapor lamp is used as excitation source and the fluorescence light is detected by a PMT, which is positioned perpendicular to the excitation source. Figure 5 is a schematic diagram illustrating the optical configuration of an AFS system.[27] A glass chimney is used for introduction of mercury vapor into the optical path. The chimney is shielded with a high flow rate of argon. A 253.7-nm interference filter is employed between the introduction chimney and the PMT to keep stray light away from the latter.

3.1.1.2 Liberation and Reduction of Mercury Since this system is used to determine total inorganic mercury (Hg^{2+}), the first requirement for performing analysis is to liberate all mercury compounds from the sample matrices and convert all organic forms of mercury to Hg^{2+} by various digestion/oxidation procedures.

For natural water sample analysis, the previously employed hot oxidizing method using permanganate–peroxodisulfate has been found unsuitable for low-level mercury determination because of the high blanks found in these reagents.[58] Bromine monochloride has been found to be an excellent oxidant and preservative for total mercury in water samples,[59] working faster and more efficiently on many organomercurials.[58,59] Hydroxylamine hydrochloride is added to destroy the excess bromine before analysis with CVAFS. This method has often been used for converting organic mercury to Hg^{2+}.[59–64]

Both open-vessel and closed-vessel digestion/oxidation techniques have been described for solid sample (soil, sediment, and tissue) analysis.[59,65–67] Open-vessel digestion results in considerable loss of organic mercury compounds by volatilization at elevated temperature or by incomplete oxidation of the sample matrix at ambient temperature. The open-vessel method is also complex and requires large amounts of glassware. These drawbacks can be overcome by using a closed decomposition system at elevated temperature. Microwave-assisted[65,66] and autoclave-assisted[67] closed-vessel digestion methods have been reported to achieve complete oxidation while minimizing losses of mercury. By using these closed-vessel methods, the preparation of the sample is effective and allows for a large number of samples to be prepared simultaneously and efficiently.

Once all forms of mercury have been converted to Hg^{2+}, the latter is reduced to elemental mercury (Hg^0) by using either acidified stannous chloride or sodium borohydride (Equations 6 and 7):

$$Hg^{2+} + Sn^{2+} \longrightarrow Hg^0 + Sn^{4+} \quad (6)$$

$$Hg^{2+} + 2NaBH_4 + 6H_2O \longrightarrow Hg^0 + 7H_2 + 2H_3BO_3 + 2Na^+ \quad (7)$$

The mercury vapor produced is carried by argon gas to the AFS instrument for detection. A typical curve obtained using this type of CVAFS system is shown in Figure 6. Peak area is generally used for quantification. This system has been successfully applied to a wide range of environmental samples, such as water,[56,60,63,66] soil,[60,66,67] and biological samples.[60,67]

3.1.1.3 Amalgamation The concentrations of mercury in natural waters are often found to be at sub-parts per trillion (nanograms per liter) levels. The determination of such low concentrations frequently requires a preconcentration step prior to AFS detection. Many of the enrichment techniques are based on the fact that mercury can be deposited easily on metals such as gold and copper.[46] The amalgam technique was used simply to improve the DLs of the cold-vapor technique. Normally, as shown in Figure 6, the mercury vapor is liberated slowly from solution and thus generates a broad signal. If instead the mercury vapor is collected by amalgamation,

Figure 6 A typical response curve for mercury analysis using CVAFS.

Figure 7 Schematic diagram of the Hg detection system. The boxed area on the left is the nondispersive resonance atomic fluorescence system. The boxed area on the right shows the two-stage gold amalgamation gas train used to introduce elemental Hg vapor (trapped on a gold column during the purging step) into the gas cell of the detection system. The carrier gas is high-purity helium, from which oxygen and Hg have been removed with trap columns. The flow rate is controlled by a needle valve positioned before the oxygen trap column and is monitored at the exit of the fluorescence cell with a flow meter. All connections are made with Teflon or silicone-rubber tubing. The gas flow direction is denoted by arrows. (Reprinted with permission from G.A. Gill, K.W. Bruland, *Environ. Sci. Technol.*, **24**, 1393 (1990). Copyright 1990 American Chemical Society.)

on a gold trap, for example, and then subsequently released by heating the trap rapidly to 500–700 °C, a higher signal-to-noise ratio (S/N) is obtained. A two-stage gold trap technique coupled with AAS for determining total mercury in environmental samples was described.[68] Gold-trap preconcentration of Hg^0 followed by AFS has also been reported.[57] Figure 7 shows a schematic diagram of the two-stage CVAFS system.[69] Because of the excellent sensitivity provided by this technique, gold-trap CVAFS is currently widely used in environmental analysis.[61,62,64,69–71] The United States Environmental Protection Agency (USEPA) has proposed, in the *Federal Register*, a method (Method 1631) for the determination of mercury in waters using oxidation, purge and trap, and CVAFS.[71] However, trace levels of mercury have been found in most reagents used. The application of this technique is often limited by the fact that mercury present as impurity in these reagents is also preconcentrated.

3.1.1.4 Miscellaneous Atomic Fluorescence Spectrometric Techniques for Total Mercury Determination LIF with ETA has been reported for total mercury determination with a 0.09-pg absolute DL. However, because of the small size of the sample to be used (only 10 µL), the concentration DL in water was only 9 ng L^{-1}.[72] This is not sufficient for total mercury determination in most natural waters, therefore limiting the application of this method.

Several flow-injection (FI) atomic fluorescence methods incorporating an on-line bromide–bromate oxidation step to determine mercury in water samples have been described.[73,74] The CVAFS-based technique uses a heated reaction coil in the FI manifold to increase the conversion of organic mercury into Hg^{2+}. However, the DL (6–25 ng L^{-1}) achieved by these techniques cannot, in many cases, meet the requirements for the analysis of environmental samples because only a small volume of sample can be used.

3.1.2 Mercury Speciation

Speciation is the identification and quantitation of the individual physicochemical forms of an element in a sample that together constitute its total concentration. It is well known that the various chemical forms (organic and inorganic) of mercury in the natural environment

behave differently, thereby affecting its biogeochemistry and toxicity to organisms. The development of analytical techniques able to distinguish different inorganic and organomercury species has been a main research area for scientists dealing with mercury in the environment. Basically, chromatography [gas chromatography (GC) and high-performance liquid chromatography (HPLC)]-based AFS, and purge and trap-based AFS are the two most widely used techniques for measuring inorganic and different forms of organomercury compounds, especially methylmercury.

3.1.2.1 Chromatographic Methods Gas chromatography/electron capture detection (GC/ECD) was traditionally used for the determination of MeHgCl or MeHgBr.[75] However, a major problem with GC/ECD is that the halogen-bearing compounds co-extracted with organic mercury interfere with the determination because of the nonspecificity of the ECD. Use of the very sensitive and selective AFS as a GC detector has successfully addressed this problem.[60,76–79] Gas chromatography/atomic fluorescence spectroscopy (GC/AFS) systems have been used for determination of methylmercury and ethylmercury in various environmental samples. A schematic diagram of the GC/AFS system is shown in Figure 8. A commercially available gas chromatograph, equipped with a megabore fused-silica column (DB-1 or BD-5), was used to separate organomercury chlorides or bromides. A pyrolyzer heated electrothermally at 800 °C was added between the column outlet and the AFS detector, converting organomercury compounds to Hg^0. The pyrolyzer was made of deactivated fused-silica tubing. The mercury atoms formed in the pyrolysis unit were transferred via a 0.5-mm i.d. Teflon tube into the AFS detector, which has a similar design to that shown in Figure 5. Argon gas was used as make-up and shield gases, and both helium and argon could be used as the GC carrier gas. A typical chromatogram obtained using this system for the determination of methylmercury and ethylmercury compounds is given in Figure 9. Column

maintenance is always an important step when a GC method is used for organomercury halide determination. With regard to the GC/AFS system, the treatment and maintenance of the GC injection port, the column, and sample preparation, have been discussed.[77,79]

In order to improve GC performance, organomercury halides can also be converted to fully alkylated derivatives by different derivatization reactions before GC/AFS analysis. Two common derivatizing methods are ethylation using sodium tetraethylborate ($NaBEt_4$) and alkylation with Gringard reagents (e.g. butylmagnesium chloride, BuMgCl).[78,80,81] The application of $NaBEt_4$ is limited because this procedure does not distinguish between ethylmercury and inorganic mercury (Hg^{2+}). The method of Grignard reactions has to be carried out in completely dried organic solvents and therefore involves tedious workup steps, which inevitably introduce analytical errors. Other derivatization reagents, such as sodium tetraphenylborate ($NaBPh_4$)[82] and sodium tetrapropylborate ($NaBPr_4$),[83] have also been studied and used for organomercury speciation by GC/AFS.[84]

Sample preparation is one of the critical steps for MeHg determination in environmental samples. For water samples, liquid–liquid extraction (LLE) with an organic solvent has been a popular preconcentration method. However, the large volumes of both water sample and organic solvent required make it impractical for real sample analysis, especially when a large sample throughput is needed. The two currently used methods are based on steam distillation[85] and solid-phase extraction with sulfhydryl cotton fiber.[77] Isolation of organomercury compounds from soil and biological samples requires

special attention because mercury species cannot be alternated during the isolation procedure. Recently, evaluation of some isolation methods for organomercury determination in soil and fish samples by GC/AFS has been reported.[79]

3.1.2.2 Purge and Trap-based Gas Chromatographic/ Cold-vapor Atomic Fluorescence Spectrometric Methods Purge and trap methods for the determination of methylmercury requires conversion of ionic $MeHg^+$ to nonionic species. The generally used method is aqueous ethylation with $NaBEt_4$. The use of $NaBEt_4$ as an aqueous derivatization agent was first reported by Rapsomanikis et al. for lead determination using a purge and trap AAS system.[86] Bloom reported an analytical method for determination of MeHg in aqueous samples by aqueous-phase ethylation with $NaBEt_4$, followed by cryogenic gas chromatography/cold-vapor atomic fluorescence spectrometry (GC/CVAFS).[87] Several studies and modifications have been conducted in terms of the trap materials and methods. In typical room-temperature trapping experiments, the volatile derivatives are trapped on a Carbotrap® or Tenax-TA® trap, thermally desorbed, separated by isothermal packed-column GC, decomposed at 700–900 °C by a pyrolyzer, and then detected by CVAFS.[88] In the cryogenic trapping method, the derivatives produced are purged by helium gas, trapped directly on a packed GC column immersed in liquid nitrogen (−196 °C), and then separated by electrothermally heating the column.[89] The ethylation approach with room temperature trapping is at present the most popular method for speciation of mercury, but ethylation followed by cryogenic trapping is also effective.

Purge and trap CVAFS is an extremely sensitive method for mercury determination. A DL (3σ of the mean blank) of $0.016\,ng\,L^{-1}$ for MeHg determination in water samples has been reported.[61] However, this method cannot distinguish between inorganic mercury and ethylmercury because they both give diethylmercury as products. In addition, severe interferences are frequently encountered in the ethylation step and MeHg artifact has sometimes been observed when environmental samples with a high inorganic mercury content were analyzed.[90]

Hydride-generation with $NaBH_4$ for MeHg analysis was reported in 1992 by Filippelli et al.[91] and Craig et al.[92] MeHg was converted to volatile MeHgH, and Hg^{2+} was converted to Hg^0 (Equations 8 and 9):

$$MeHg^+ + NaBH_4 \longrightarrow MeHgH \quad (8)$$

$$Hg^{2+} + NaBH_4 \longrightarrow Hg^0 \quad (9)$$

Several research groups have demonstrated the presence of MeHgH in the gas phase by using different techniques.[91,92] Hydride-generation followed by CVAFS was reported for mercury determination in various environmental samples.[93]

3.1.2.3 Miscellaneous Atomic Fluorescence Spectrometric Techniques for Mercury Speciation AFS can also be used as an HPLC detector. Hintelmann and Wilken described a method for the determination of organomercury compounds using HPLC with on-line AFS detection.[94] The organomercury compounds separated by HPLC were converted to Hg^0 in a continuous-flow system by an oxidizing, and a subsequent reducing, solution. The Hg^0 generated was separated in a gas–liquid separator and swept into the cell of an AFS detector by a stream of argon. This system was successfully used to separate eight organomercury compounds. The absolute limit of detection (LOD) for MeHg was reported to be about 0.02 ng. This corresponds to a concentration LOD of $0.8\,\mu g\,L^{-1}$ for a 25-μL injected volume. Although HPLC has an advantage over GC in that formation of volatile derivatives is not necessary, the LOD achieved do not appear to meet the requirement for most environmental samples, especially for natural waters.

Recently, Cai et al. reported an analytical method involving ethylation using $NaBEt_4$ followed by solid-phase microextraction (SPME) and GC/AFS detection for the rapid determination of methylmercury in fish.[81] The procedure involves aqueous ethylation with $NaBEt_4$ and adsorption of Et_2Hg and MeHgEt from aqueous solution or headspace on a fiber coated with poly(dimethylsiloxane). After retraction of the fiber into a syringe needle, the analytes are desorbed in an injection port of a gas chromatograph, separated, and detected by AFS using the system shown in Figure 8. At present this procedure cannot be used for the determination of MeHg in natural waters owing to the limited sensitivity.

3.2 Hydride-forming Elements

Many environmentally important elements, such as arsenic, selenium, bismuth, antimony, tellurium, germanium, tin, lead, and mercury, can form volatile and covalent hydrides with ''nascent'' hydrogen. Hydride-generation is a preferred technique when hydride-forming elements are to be analyzed by atomic spectrometry. The advantage of volatilization as a gaseous hydride clearly lies in the separation and enrichment of the analyte element and thus in a reduction or even complete elimination of interferences.[46] Since many features of these hydride-generation techniques are similar between different elements in terms of the reactions and instrument designs, the analytical aspects of all these elements using

hydride-generation followed by AFS are discussed in this section. Of course, these elements can also be determined using other AFS techniques, which will be summarized in the next section along with the determination of other non-hydride-forming elements by AFS.

Since Holak in 1969 first applied hydride-generation for the determination of arsenic using AAS,[95] a number of papers have been published describing modifications and optimization of the techniques. Currently, the number of metals and metalloids that can be determined by the hydride-generation technique has increased to about nine (arsenic, selenium, bismuth, antimony, tellurium, germanium, tin, lead, and mercury). Although the major research was carried out using AAS for detection,[46] most of the elements have also been studied using hydride-generation followed by AFS detection. Tsujii and Kuga in 1974[96] were the first to describe hydride-generation coupled to nondispersive AFS. They reported a DL of 2 ng for arsenic analysis. Thompson in 1975[97] was the first to apply a dispersive AFS system for the determination of arsenic, selenium, antimony, and tellurium after hydride generation. DLs using this system ranged from 0.06 to 0.1 $\mu g\,L^{-1}$.

Although various metal–acid reactions (e.g. Zn–HCl) have been used as a means of producing hydride, $NaBH_4$ is currently used exclusively. By using $NaBH_4$ as the reductant, the technique is easy to automate, since only solutions are involved, so that a high sample throughput can be achieved. In contrast to the manual injection of $NaBH_4$ or sample solution into the reaction, all the solutions can be delivered by a continuous-flow hydride-generation system.[12] Such a system is currently commercially available.[14] The design of this system is similar to that of the cold-vapor generation system used in CVAFS for mercury analysis as shown in Figure 4.

Once the hydride has been formed and driven out of the solution, it can be directly delivered by an inert gas such as argon to the atomizer where it is excited by a fluorescence light source and measured by a detector such as solar blind PMT. The hydride produced can be first collected in a trap cooled in liquid nitrogen before it is warmed up to vaporize it for measurement. The configuration of this design is similar to that used in the purge and trap system for mercury determination discussed above. For routine analysis, the former (direct) method offers the advantage of a higher sample throughput and easy operation. However, the latter approach provides the highest yield and best sensitivity.[46] Both procedures have been widely used in HG/AFS.

When determination is needed for different ionic species of elements present in a sample, various types of HPLC are employed to separate these forms of compounds, which are then subjected to hydride generation, followed by direct or purge and trap AFS detection. Sometimes an on-line decomposition step is added between HPLC and hydride generation to convert non-hydride-forming species into hydride-forming species. A chemical reagent, such as potassium peroxodisulfate, assisted by UV photochemical oxidation or microwave digestion has been used for this purpose.[98–101]

Although occasionally an electrothermal atomizer has been used, an argon–hydrogen diffusion flame atomizer is the usual choice because of very low background radiation, easy decomposition of hydrides in such a low-temperature flame, and the low quenching effect in the argon-supported flame. The atomization mechanisms of hydrides in different atomizers have been studied extensively. Evidence has been presented showing that the atomization of hydrides in a cool argon–hydrogen diffusion flame is not the result of a simple thermal dissociation process.[12,35,46] Dedina and Rubeška concluded that atomization is brought about by free radicals produced in the primary reaction zone of the oxygen/hydrogen flame according to Equations (10–12):[35]

$$H + O_2 \longrightarrow OH + O \tag{10}$$

$$O + H_2 \longrightarrow OH + H \tag{11}$$

$$OH + H_2 \longrightarrow H_2O + H \tag{12}$$

It can be shown that the concentration of H radicals is several orders of magnitude higher than that of OH radicals. Taking selenium as an example, the atomization is via a two-step mechanism with the predominating H radicals (Equations 13 and 14):

$$SeH_2 + H \longrightarrow SeH + H_2 \tag{13}$$

$$SeH + H \longrightarrow Se + H_2 \tag{14}$$

It has already been shown that there is a large number of H radicals present in an argon–hydrogen diffusion flame, so the same reaction mechanisms can be expected.[46]

As with any other technique, HG/AFS suffers from interferences. Welz[46] gave an extensive discussion about various interferences encountered in hydride-generation methods. However, the sensitivity of the AFS system allows dilution of the sample so that the interferences are reduced significantly. Spectral interference is not a problem for HG/AFS because the analyte element passes into the atomizer as gaseous hydride, while concomitants normally remain in the reaction vessel. In most currently used nondispersive AFS detectors, an interference filter is located between the atomizer and the PMT, to reduce the flame background and emissions from the excitation source that do not produce intense fluorescence lines.[12] The flame background can also be minimized by choosing suitable flow rates of gases. Kinetic interferences are

caused by varying rates of development or liberation of the hydride from solution. These interferences only occur in the direct hydride-generation system, and not in the purge and trap system. A typical kinetic interference is the retardation of hydride liberation because of the sample matrix effect. Chemical interferences are perhaps the most frequently encountered problem. It appears that transition metals interfere significantly with hydride-generation reactions.

3.2.1 Arsenic

Arsenic was the first element to be determined using the HG/AFS technique.[96] A number of papers have been published on arsenic determination in environmental samples. Azad et al.[102] described a procedure for the determination of arsenic in soil digests in which arsine was generated with $NaBH_4$, passed to an argon–hydrogen air-entrained flame and an atomic fluorescence signal, excited by a modulated EDL, and measured using nondispersive AFS. The authors reported a DL of $3\,\mu g\,L^{-1}$ calculated as the mass of arsenic required to produce a S/N of 2 for the atomic fluorescence signal. Most papers published in the past utilized an EDL as the excitation source because this type of lamp provides intense and narrow lines. However, the EDL is often unpredictable in use and requires careful temperature control to achieve good stability. A BDHCL seems to be a reliable high-intensity excitation source and this type of lamp has been used in commercial AFS instruments. Corns et al.[12] described a fully automated continuous-flow hydrogen generation AFS system for the determination of hydride-forming elements, principally arsenic and selenium. A minature argon–hydrogen diffusion flame was used as the atomizer and a BDHCL was used as the excitation sources. The hydrogen for the flame was chemically generated as a byproduct of the $NaBH_4$ reduction. Fluorescence wavelengths of interest were selected using an interference filter. A solar blind PMT was used as the detector. A DL (3σ) of $0.1\,\mu g\,L^{-1}$ was reported for arsenic.

To date, about a dozen arsenic compounds have been found in environmental samples.[101] Extensive studies on the toxicity and biogeochemistry of arsenic have clearly depicted the importance of the chemical speciation of this element. To determine these different forms of arsenic in environmental samples, a powerful separation technique, such as HPLC, has to be used. A number of analytical systems based on high-performance liquid chromatography/hydride-generation/atomic fluorescence spectrometry (HPLC/HG/AFS) have been reported. Recently, Gomez-Ariza et al.[98] described an anion-exchange HPLC/HG/AFS system for the speciation of arsenite, arsenate, dimethylarsinic acid (DMAA), and monomethylarsonic acid (MMAA). The products of hydride-generation of arsenite, arsenate, DMAA, and MMAA are arsine (AsH_3), arsine, Me_2AsH, and $MeAsH_2$, respectively. DLs of 0.17, 0.38, 0.45 and $0.30\,\mu g\,L^{-1}$ were reported for arsenite, arsenate, DMAA, and MMAA, respectively. A schematic diagram of this system is shown in Figure 10. Arsenobetaine, a non-hydride-forming species of arsenic, was also determined by introducing an on-line photooxidation step after the chromatographic separation. Le et al.[100] described an on-line microwave derivatization coupled with HPLC/HG/AFS for arsenic speciation. They studied the separation of 11 arsenic compounds by using ion-pair chromatography at 30, 50, and 70 °C column temperature and found that the use of elevated column temperature improved the separation efficiency and dramatically reduced the chromatographic time for some arsenic species. This speciation technique was successfully applied to a study of metabolites of arseno sugars present in commercial seaweed products. A typical chromatogram obtained for speciation of seven arsenic compounds is shown in Figure 11.

Hydride-generation followed by purge and trap AFS can also be used for speciation of hydride-forming arsenic

Figure 10 Operating scheme of the HPLC/HG/AFS system for arsenic speciation. (Adapted from J.L. Gomez-Ariza, D. Sanchez-Rodas, R. Beltran, W. Corns, P. Stockwell, *Applied Organomet. Chem.*, **12**, 1 (1998). Copyright 1998 John Wiley & Sons Limited. Reproduced with permission.)

Figure 11 Chromatogram of seven arsenicals obtained on a reversed-phase C_{18} column (300 × 3.9 mm i.d., 10-μm particles) with 10 mM hexanesulfonate, 1 mM tetraethylammonium hydroxide, and 0.5% methanol as eluent (pH 4.0). Microwave digestion combined with hydride generation and AFS was used for detection. Column temperature, 70 °C. Peaks: 1, arsenate (10 ng); 2, arsenite (40 ng); 3, arsenobetaine (15 ng); 4, MMAA (10 ng); 5, DMAA (40 ng); 6, arsenocholine (15 ng); 7, tetramethylarsonium (40 ng). species such as arsenite, arsenate, DMAA, and MMAA. A pH-selective hydride-generation process should be used.[103] This process comprises two steps. First, arsenite is reduced to AsH_3 by $NaBH_4$ at pH 6. The product is swept out of the solution and collected with a cooled trap under liquid nitrogen. The trap is then allowed to warm to room temperature and the arsine is released into the AFS system for detection. Second, arsenate, DMAA, and MMAA in the sample solution are reduced to the corresponding arsines at pH 1, then followed by purge and trap AFS detection.

3.2.2 Selenium

The AFS determination of selenium was first reported by Dagnall et al.[104] using a dispersive spectrometer equipped with an air–propane flame giving a DL of 0.25 μg mL^{-1} of selenium on aspiration of aqueous solution using a pneumatic nebulizer. A dramatic improvement in DL (10 μg L^{-1}) was obtained by using a similar experimental arrangement, but using an argon–hydrogen diffusion flame and the hydride-generation technique.[105] This HG/AFS system was used for the determination of selenium in soil samples. A current commercially available HG/AFS instrument[12] utilizes a BDHCL as the excitation source and also an argon–hydrogen diffusion flame as the atomizer. A DL (3σ) of 0.05 μg L^{-1} was reported. A standard reference material (SRM) for trace elements in water, SRM 1643d from the National Institute of Standards and Technology (NIST) (Gaithersburg, MD, USA), was used to test the performance of this system.[84] The concentration of selenium was found to be 11.40 ± 0.07 μg L^{-1} ($n = 3$), which was in close agreement with the certified value of 11.43 ± 0.17 μg L^{-1}.

Selenium can also exist as different forms, both inorganic and organic, in environmental samples. Volatile organic selenium compounds can be directly determined using purge and trap followed by AFS without derivatization (see the next section). The determination of inorganic forms, Se(IV) and Se(VI), at low concentration levels is generally carried out using the hydride-generation technique. Since only Se(IV) is able to generate the hydride, if speciation data are required two procedures are usually used. In the first procedure, the sample has first to be analyzed without pretreatment, which provides the Se(IV) concentration. Then the sample is treated by heating it with 6 mol L^{-1} hydrochloric acid, which reduces any Se(VI) to Se(IV). The analysis is performed again, to give a total concentration of inorganic selenium present in the sample. The concentration of Se(VI) is then calculated by difference. The obvious disadvantage of this method is its indirect determination of Se(VI), which involves the errors induced by determination of Se(IV) and total inorganic selenium.[106] The speciation of Se(IV) and Se(VI) can also be carried out using HPLC separation followed by detection with different detectors.[106,107] Pitts et al.[99] recently described an on-line method for determination of inorganic selenium species in aqueous samples using HPLC/HG/AFS. Separation of these species was achieved using HPLC, after which the analyte was acidified, and passed through an on-line microwave system. The latter stage left the Se(IV) unaltered, but transformed Se(VI) to Se(IV). The selenium hydride was then determined using an AFS detector. DLs of 0.2 and 0.3 μg L^{-1} were reported for Se(IV) and Se(VI), respectively.

3.2.3 Other Hydride-forming Elements

In addition to arsenic and selenium, other elements such as antimony, bismuth, tellurium, germanium, tin, and lead have also been determined using HG/AFS. It should be noted that the arrangements of the instruments used for the analysis of these elements are identical with those for arsenic and selenium except for the utilization of a corresponding excitation source and wavelength-selection system. Both dispersive and nondispersive AFS have been used.[56,97] Kobayashi et al.[108] published the first paper on the determination of bismuth using an HG/AFS system. They used an argon–hydrogen diffusion flame as the atomizer and a microwave-excited EDL as the excitation source, and achieved a DL of 5 μg L^{-1} or 0.1 ng of bismuth. Nakahara et al.[109]

described an analytical method based on HG/AFS for the determination of tellurium using an argon–hydrogen diffusion flame and an EDL excitation source. The comparison of the Zn and $NaBH_4$ reduction methods was discussed. The best attainable DLs for tellurium were 0.1 μg L^{-1} (2 ng) and 1.5 μg L^{-1} (30 ng).

Nakahara et al. have also conducted a series of studies on the determination of other hydride-forming elements[110,111] using hydride generation coupled with nondispersive AFS. D'Ulivo and Papoff[112] described a method using nondispersive AFS combined with hydride generation for the determination of lead. They used a radio-frequency-excited EDL as the excitation source and a small argon–hydrogen flame as the atomizer. The DL was 0.06 μg L^{-1} and the calibration curve was linear up to 300 μg L^{-1}, superior to HG/AAS or inductively coupled plasma atomic emission spectrometry (ICP/AES). Using a similar HG/AFS system, D'Ulivo et al.[32] determined dialkyllead and trialkyllead. The DLs obtained for trimethyl, triethyl, dimethyl, and diethyllead (3σ) were 3–5 ng L^{-1}. Although HG/AFS is an appropriate analytical technique for the determination of these hydride-forming elements, its application in environmental analysis seems to be very limited. This is due, in part, to the fact that until recently no commercial HG/AFS instruments were available. Most of the research was carried out using laboratory-made systems. However, a continuous-flow HG/AFS system, recently made commercially available, provides a capability for arsenic, selenium, antimony, tellurium, and bismuth determination with a DL in the sub-parts per billion region.[12,14,56]

3.3 Non-hydride-generation Methods

3.3.1 Laser-induced Fluorescence

Determinations of hydride-forming elements in environmental samples are usually carried out using HG/AFS because of its high sensitivity and simplicity. Another very sensitive type of AFS, which has been used for the determination of many elements (both hydride-forming and non-hydride-forming), is LIF. LIF provides the lowest absolute DLs for a number of elements.[23]

Although different types of atomizers, such as flame, plasma, and electrothermal, can be coupled with LIF, it appears that the most sensitive practical measurements by LIF are performed in those ETA instruments, such as graphite-tube furnaces, that are currently used in AAS. With an ETA as atomizer, absolute DLs below femtogram level can be obtained experimentally for some elements. Omenetto[23] collected pertinent data for 22 elements investigated with LIF/ETA and the DLs were compared with those given by inductively coupled plasma mass spectrometry (ICP/MS). For most elements, the data obtained using LIF/ETA are superior to those obtained using ICP/MS. Recently, a DL of 10 fg mL^{-1} (100 ag absolute) was reported for lead determination in whole-blood samples using LIF/ETA.[19] A schematic diagram of the experimental design for LIF/ETA is shown in Figure 12.

Figure 12 Experimental design for LIF/ETA. (Reprinted with permission from E.P. Wagner II, B.W. Smith, J.D. Winefordner, *Anal. Chem.*, **68**, 3199 (1996). Copyright 1996 American Chemical Society.)

LIF/ETA has been used for the determination of a number of elements in various environmental samples. Bolshov et al.[24] reported the results for the determination of cadmium in Antarctic and Greenland snow and ice by LIF/ETA. The DL was found to be 0.5 fg or 0.01 pg g^{-1} using a 50-μL sample volume. Silver was determined in seawater by LIF using novel diffusive graphite-tube ETA.[113] A 10-μL volume of sample was applied to a small graphite boat attached to one of the graphite electrodes and inserted into the graphite tube, which was then sealed by the electrodes and heated. The vaporized silver passed through the graphite wall and was excited by a laser beam a few millimeters above the surface of the tube. A DL of 90 fg for 1 : 1 diluted seawater was obtained. Other examples of recent applications of LIF/ETA include the determination of aluminum and lead[114] in atmospheric aerosol samples, antimony[40] in biological and environmental samples, bismuth,[115] cobalt,[116] and lead[25] in seawater, thallium[117] and lead[118] in natural water, and mercury[119] in soil.

LIF coupled with flame atomization has also been used for environmental sample analysis. Zhou et al.[21] described methods for the determination of cobalt, copper, lead, manganese, and thallium in Buffalo River sediment using flame LIF. A standard, long-path flame atomic absorption burner was used and DLs for cobalt (2 ng mL^{-1}), copper (2 ng mL^{-1}), lead (0.4 ng mL^{-1}), and thallium (0.9 ng mL^{-1}) were reported.

One of the major problems facing the future use of LIF instruments is that lasers are difficult to use. They are costly and require highly skilled operators. This certainly limits the development of commercially available instruments.

3.3.2 Atomic Fluorescence Spectrometry as a Chromatographic Detection Method

AFS can be conveniently used as a detection method for chromatography, such as GC and HPLC. Details can be found in an excellent paper by D'Ulivo,[7] who summarized the research regarding the utilization of AFS in chromatographic detection. Brief information is given below.

Van Loon et al.[120] first described a method for the simultaneous speciation of several elements using an atomic fluorescence spectrometer as an element-specific detector for chromatography. A three-channel nondispersive atomic fluorescence spectrometer with an HCL as the excitation source and a nitrogen-sheathed air–acetylene flame as the atomizer was used. It was interfaced to an HPLC system by direct connection of the column outflow to the nebulizer capillary of the burner. The column flow rate was compatible with the nebulizer flow rate. The technique was successfully applied to the simultaneous detection of several metals as their EDTA (copper, zinc, nickel), glycine (copper, zinc, nickel), and trien complexes. More research has been carried out to study metal speciation using different models of coupling of HPLC with AFS.[121]

Coupling AFS to GC greatly simplifies the task of the atomizer since the effluents supplied to the AFS system are already in the vapor phase.[7] Different types of atomizers have been designed and applied to the speciation of metals.[122] D'Ulivo and Papoff[123] described a technique using GC coupled with multichannel nondispersive AFS for the simultaneous determination of alkyllead, alkyltin, and alkylselenide compounds. Recently, Pécheyran et al.[124] described a GC/AFS method for the determination of ultratrace volatile selenium species in aqueous solutions. The method, optimized for field measurements of volatile selenium species in aquatic environments, involved a shipboad purge of the water samples collected under clean conditions, a cryogenic trapping stage followed by separation of the analytes by low-temperature chromatography. Under routine operating conditions, absolute DLs of 4 and 4.5 pg of Se for Me_2Se and Me_2Se_2 were obtained, respectively.

It is expected that recent developments will strengthen the role of commercial AFS in the determination of trace elements in environmental samples. Indeed, AFS has already been shown to be the most sensitive and important detection technique for mercury determination, especially for samples with low concentration levels.

4 CONCLUSIONS

Clearly, the most important and widely used AFS systems in environmental analysis have so far been CVAFS for mercury and HG/AFS for the determination of the hydride-forming elements. In practical terms, for environmental and other areas of analysis, the broader adoption of AFS will depend on the introduction of standardized commercial instrumentation and the ability to compete with other techniques that are commonly used, such as AAS, AES, and ICP/MS. Currently, several companies manufacture AFS detectors used either for mercury or hydride-forming elements, or both. These AFS detectors are of simple design and easy operation. Most importantly, these cost-effective instruments provide excellent DLs for some environmentally important elements, such as mercury. Important progress is, therefore, expected in using these instruments for environmental analysis.

Although LIF has practical limitations at present, such as high cost and difficult operation, the exceptional low DLs achieved using LIF for some elements are very attractive. This is especially true when only small sample amounts are available.

ACKNOWLEDGMENTS

It is a pleasure to acknowledge the encouragement given to me during preparation of this article by Dr Rudolf Jaffé. Special thanks are due to Anita Holloway for her assistance in the preparation of the manuscript. I wish to express my thanks to the many authors and publishers who have given permission for the reproduction of figures from the original literature. This is SERP contribution number 106.

The most difficult samples to analyze are those derived from biological sources. The analysis of biological samples requires the ability to extract and isolate a wide range of environmental pollutants from an even wider range of matrices, from simple bacteria to tissues and fluids from humans, from fungi to the complex tissues and structures of the plants and products that compose the food chain. These matrices comprise a variety of cells, connective tissues and fibers, fluids and related materials that introduce literally thousands of different organic and inorganic compounds to every analysis effort. In order to recognize and assess the nature and severity of pollution and its impact on humans as well as the flora and fauna that constitute our environment, highly efficient and selective methods for the extraction and cleanup of such samples must be developed. New developments in analytical science have been brought to bear on this problem, speeding the extraction and analysis process while making the resulting analyses more sensitive and selective. The present article examines the historical approach to the extraction and cleanup of biological samples for the analysis of pollutants, and reviews recent advances in technology and methodology that have proven applicable to this field.

1 INTRODUCTION: THE EXAMINATION OF BIOLOGICAL SAMPLES TO DETERMINE THE EXPOSURE AND IMPACT OF POLLUTANTS

The composition of biological samples ranges in complexity from the simplest liquids to the most intricate mammalian tissues. It encompasses everything from bacteria and viruses to plant to animal, ranging in development from single cell, spore, seed or egg to adult. The compounds that constitute the matrix of each type in this variety of potential samples for environmental analysis also run the gamut from simple molecules and elements to the most elaborate of proteins, carbohydrates and, of course, nuclear DNA. It is of interest to identify and measure these compounds as such; assaying these naturally occurring molecules of which biological materials are composed is task enough. However, humankind has added to this task the need to assay all of the other compounds we introduce into the natural process; agrochemicals (herbicides, pesticides), pollutants (polychlorinated biphenyls, (PCBs) polyaromatic hydrocarbons, (PAHs) etc.) and, for food animals, residues of veterinary drugs, all needles in a sample matrix haystack.

The history of all analytical science is mirrored in environmental chemistry, with new technologies being applied as they are developed for each of the needs for analysis in the field. Often the new technology has

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

been developed by chemists already in the area, applied in an effort to solve the many difficult analytical tasks with which they were, and continue to be, presented in performing environmental analyses in biological samples. Many of the problems faced in this and other areas of the analytical sciences are the same, however, and involve the need to perform adequate sample preparation, homogenization and disruption, sample/target analyte(s) isolation, analyte(s) resolution from co-extracted sample components and analyte(s) detection and quantitation.

To begin to analyze a biological sample for a compound of environmental interest, certain steps must be taken to assure the quality and reliability of the result. The value of this analytical result is directly related to the procedures used for sample preparation. Sample preparation is not merely the steps required in the homogenization, extraction and cleanup prior to introduction to an instrument. It also requires consideration of the level of documentation, appropriate procedures for sample collection, storage and shipment, assuring the stability of the sample and the target analytes and the processing of the sample necessary before extraction begins.

The methods applied for these processes require the development and thorough validation of the procedures to be employed. As well as this being simply good laboratory practice (GLP), it must also be noted that the results from environmental analyses are often used in litigation and may prove essential to making decisions concerning threats to the public health. Thus, regulatory authorities at many levels of government have established, through law and regulation, analytical procedures and methods that have been proven to be highly reliable. These ''official methods'' have withstood the test of time, as well as the courts, but have been modified over the years to incorporate new technologies and approaches. Such modifications must, however, prove to be equivalent to or better than the techniques they replace.

The trend in sample preparation and cleanup is away from the use of procedures that require large volumes of extracting solvent, large sample size and complicated and expensive glassware and/or instrumentation that have characterized ''classical'' methods for environmental analysis. Such methods are being replaced by techniques that require smaller sample sizes, offer generic extraction techniques and that can be readily automated to speed obtaining the results of an analysis. The field is further evolving to include the use of immunoassay, affinity chromatography, biosensing and other analytical advances to even further simplify or completely eliminate the processes previously required for sample preparation and cleanup. Such advances are being assisted by the new generation of analytical instruments that provide greater sensitivity, selectivity and speed of analysis.

The present article will address the general processes and principles involved in the preparation and cleanup of biological samples prior to analysis for environmentally relevant pollutants. It will address these issues from a historical perspective, examining ''official'' methods for the analysis of pollutants and discussing newer techniques that are slowly replacing more classical approaches. It is noted here that it is not possible to cover every biological matrix or environmental pollutant of interest and that each combination of target analyte and sample can present unique complications. Indeed, the analysis of thousands of environmental pollutants, ranging from alar on apples to PCBs in the hepatopancreas of crayfish, and the variety of biota, encompassing all five kingdoms that are exposed to them, constitute a major challenge to the analytical chemist. The methods developed to isolate, detect, identify and quantify these compounds are, however, essential to maintaining the health of the food supply and our environment and provide us with the capacity to identify, regulate and correct environmental hazards.

Much of the information, references and examples presented will be based on analyses conducted in aquatic species for environmental pollutants such as chlorinated pesticides, herbicides, PAHs and PCBs. Attention to single compounds and specialized protocols will not be addressed here. Nevertheless, the principles involved do address both the problems and the solutions to be encountered in dealing with biological samples in general in environmental analyses.

1.1 The Exposure of Flora and Fauna to Pollutants

Pollution is a relative term. Natural processes, such as forest fires, thermal venting, leaching of metals and minerals by groundwater and rain, and photochemical reactions in the atmosphere, are all processes that can contribute to alteration of the natural chemical state of a given ecosystem. This alteration of the environment can be seen as a pollution of the native molecular scheme. Changes in this chemical scheme can be measured relative to its initial state or relative to other areas to assess the degree of change.

The evolution of human technologies and the ever-increasing population of the planet have, however, added significantly to these natural processes. Humankind has also introduced many molecular species never before seen in the natural environment.

The use of fossil fuels, the industrialization of many nations' economies, the industrialization of agriculture, our struggles to handle our manufacturing and human wastes have spiraled as we have sought a higher standard of living through increased production. These efforts for our well-being have often been at the expense of the flora and fauna whose ancestors readily predated our own on

this planet. It has also been at our own peril. It has become a vicious cycle of the interactions of the environment's natural processes with humankind's introduction of unnatural substances, polluting and contaminating the cycle of life.

It is perhaps ironic that the justification for the original production and use of many herbicides, pesticides and other manufactured pollutants, such as their environmental or thermal stability, intended toxicity toward a particular pest, etc., eventually led to their becoming a continuing threat to the environment. For example, while the chlorinated pesticides were valuable for crop and animal agriculture, they also persisted in the environment, being highly stable to most aspects of environmental degradation. From the producers' point of view this was advantageous, reducing the frequency of application of the pesticide and the costs inherent in the process. However, as the toxicity of many of these compounds became evident, this persistence became the very cause for the removal of many such products from the market in the USA. Unfortunately, large quantities of many of these compounds, as well as others, have continued to be used in developing countries around the world.

Of further concern has been the level of these compounds that has accumulated in the environment from spraying, from legal and illegal dumping, and from sequestration in soils and sediments from which continuing diffusion of these materials into various habitats and resources can occur. Since many of these compounds are highly lipophilic, they tend to accumulate in fatty as well as other tissues of animals that compose the food chain. For aquatic environments, even coastal and deep-sea species have been found to contain detectable levels of many such compounds on a decreasing concentration gradient as one moves farther from land and away from river-influenced bays, gulfs and ocean currents.

The persistence of many classes of pollutants, their magnification through bioaccumulation and the concerns for their known and unknown toxicity require that state, federal and international monitoring programs provide mechanisms for assessment and remediation. However, state, national and international programs have not always proven to be capable of being integrated. This is in part due to the variety of biological matrices that one encounters when dealing with analyses of pollutants. It has also led to a degree of confusion in the field and has underscored the need for new methodology that can rapidly assess a pollution problem. This demand is further heightened by the fact that adequate monitoring will require the analysis of more samples for more compounds in shorter time frames than existing methods can currently handle.

The role of the analytical chemist in this situation is to provide methodology to identify and measure the compounds that we define as pollutants. Identification and measurement are the first steps in recognition and amelioration of the problem.

1.2 Biological Sentinels for Monitoring Pollution

We can readily acknowledge the exposure of the environment to contaminants. We may then also note that these environments are filled with native plants and animals, which have unwittingly offered themselves as sentinels to their own, and to our, exposure. Thus, the practice of analyzing biological matrices from the field for environmental contaminants has been used extensively as a general environmental monitoring strategy, accompanied by measurements in soils, sediments, water and air. We have extended this strategy by actually placing particular species in an area to further allow assessment of exposure under more controlled conditions. The use of such an approach, taking advantage of the ability of plants and animals to bioconcentrate pollutants, is defensible in the sense that we are most concerned about the impact of pollution on living beings and, most selfishly, ourselves. Furthermore, such efforts may be justified based on the fact that the levels of environmental contaminants in water are often too low to detect or quantify by conventional analytical methods, requiring significant efforts at concentrating residues. The effort to measure contaminants in water can be further complicated if the contamination originates from a point source into a moving stream or river. As a result, the use of biomonitors or environmental sentinels has been proposed as a method to determine the status of contamination by chemicals at both the tissue residue and the genetic level.[1] This idea takes advantage of the bioaccumulating ability of some organisms for lipophilic organic chemicals, which is the category into which many of the environmental pollutants fall. For example, mussels (Mytilus species, for example) have been used in the past in the United States Environmental Protection Agency (USEPA) ''Mussel Watch'' program[2] as convenient, sedentary sentinels. The high lipid content and water-filtering function and capacity of both mussels and oysters make them ideal monitors of aquatic pollution. They may also be placed in baskets or pens to protect them from predators and strategically located in a grid pattern to obtain more controlled data.

Investigations have also used other species to monitor environmental contamination in water.[3,4] Catfish (*Ictalurus punctatus*, for example) are also a logical model species to investigate new analytical sample preparation techniques since they are filter feeders, bottom dwellers and an important food source.[5] Thus, any sedentary or relatively stationary species may serve as a living record of past exposure. Taken in combination with other data from soils, sediments, water, etc., this can provide an

interpretation of the pollution history and status of an area.

Vegetables, fruits, mushrooms, legumes, cereals, etc. are also exposed to a variety of herbicides, pesticides and water- or wind-borne pollutants. Such sentinels are completely stationary and can provide an exposure history when examined over a large area in the field or after collection and processing. Of most immediate concern, however, is their entry into the food chain.

Regardless of the species, all plants, animals and living organisms constitute the range of biological samples that can be analyzed to assess environmental pollution. They, as well as we, are all sentinels to our environment, all canaries in the mine.

1.3 Analytical Chemistry's Role in Responding to Environmental Pollution

How do we determine when a system has become polluted? How do we define the source and the nature of the pollutants involved? The ability to detect and assess the impacts of toxic wastes on various environments and the species that populate them is dependent on the ability to perform analyses of the water, sediments, soils and tissues of the affected biota. Such analyses must encompass the attributes of high efficiency of isolation, adequate sensitivity, specificity and linearity of response to whatever system of detection and identification is employed. Such methods must be of high quality, accurate, precise and reproducible, supplemented by a high degree of documentation, quality assurance (QA) and quality control (QC). Such methods must be thoroughly documented and validated as being able to be conducted in a number of different laboratories. In the USA this undertaking has been assumed by the government. In association with professional organizations, private industry and universities, there has been success in bringing some order to the chaos. This does not imply perfection, however.

While there has been significant progress in the recent past in the ability to extract and analyze pollutants in water, mainly due to solid-phase extraction (SPE)-disc technologies and advances in instrumentation ease of use and sensitivity, there has yet to be such dramatic progress in performing analyses in biological samples. The preparation and cleanup of such samples for submission to advanced analysis by our evolving instrumentation has remained a difficult and cumbersome task.

Most methods recommended by various governments for dealing with biological samples involve the classical approach of sample disruption, solvent/solvent extractions, back-extractions and column chromatographic cleanup steps. Analytical chemists have long recognized that such methods are limited in their turnaround or response times and expend large volumes of solvent and personnel hours, especially when they must be applied to large numbers of samples. The solvent use is of particular concern since many of the methods require the use of liters of solvent even for a single sample, solvent that is often evaporated into the atmosphere, polluting thousands of liters of air. Discarded solvent must be handled as hazardous waste, adding large volumes of solvent residues to already burdened disposal sites and greatly adding to the overall costs of solvent disposal, not to mention the initial costs of solvent purchase and the unknown costs of personnel exposure. Many of these methods may, in the final analysis, contribute more pollution to the environment than they ever detect. For these reasons future directions for the analyses of toxic wastes and pollutants in general will proceed through the development of simple, generic and environmentally friendly methods that require little or no solvent and that are capable of providing data in rapid response to inquiries concerning contamination and waste remediation.

2 ENVIRONMENTAL REGULATIONS AND METHODS: THE RESPONSE OF GOVERNMENTS TO THE PROBLEMS OF POLLUTION

The final expression of frustration in dealing with any serious problem is the establishment of a governmental agency to study and attempt to control the problem. Laws are passed and regulations are written. Once the regulations and laws are put into practice, bureaucrats are imbued with the authority to interpret them and to write further regulations to regulate the regulations already in place. Then come the judiciary to settle the disputes between the regulators and the regulated. On an international basis the situation can become even more complicated as the laws of one nation clash with those of its neighbor. However, pollution is at once local, national and international, with all nations sharing the same air, the same water and the same global environment in the end.

2.1 The Development of Laws, Regulations and Regulatory Agencies for Monitoring Environmental Pollution

A number of legislative events enacted in the USA since the late 1960s have initiated the development and standardization of analytical methods for environmental contaminants in general. An overview of early environmental legislation has been presented by Foster.[6] The first modern major legislative act approved in 1969 by the United States Congress was the National Environmental Policy Act (NEPA) and the Environmental Quality Improvement Act (EQIA) of 1970. Shortly thereafter,

Congress created the USEPA from which to coordinate government action and focus authority for protecting the environment. As a result, the USEPA implemented four major pieces of environmental legislation. Amendments to the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) of 1947 and the Federal Water Pollution Control Act (FWPCA) of 1948, in 1972 placed them under the control of the USEPA. Another piece of legislation in 1972 was the enactment of the Marine Protection Research and Sanctuaries Act (MPRSA) implemented to expand the United States protection of the open ocean to the extent of their authority. In 1976, the Toxic Substances Control Act (TSCA) gave the USEPA regulatory control over commercial chemical use. Other significant enactments of environmental legislation since then have been Resource Conservation and Recovery Act (RCRA) and Superfund.

Ultimately, three federal agencies participate in the responsibilities of regulating pesticides and related compounds for the United States. The USEPA (see above), the United States Department of Agriculture (USDA), and the Food and Drug Administration (FDA). The USEPA has the responsibility of approving the use of pesticides as well as establishing residue tolerances in foods.[7] The USDA enforces these tolerances in meat and poultry and the FDA is in charge of enforcing residue tolerances for any other food products shipped in interstate commerce[8] although the FDA does play a role in aiding the USEPA in establishing residue goals.[9]

Currently, the FDA conducts an extensive residue monitoring program each year involving the analysis of over 20 000 samples using multiple residue methods. An overview of this program and the results since 1978 has been described.[10–14] Data collection and dissemination programs have been implemented by the FDA.[15,16] Seafood and seafood products, although not required to pass unified, continual federal inspections by the FDA, remain a concern with the public because of the specter of environmental contaminants[17] occurring in the open ocean and off the coasts of other nations as well as the USA. In 1965, the United States Bureau of Commercial Fisheries began the National Pesticide Monitoring Program, which lasted until 1972, to monitor chlorinated pesticide residues in shellfish populations off the coast of 15 states.[18] The results demonstrated that 1,1,1-trichloro-2,2-bis[*p*-chlorophenyl]ethane (DDT) (CAS 50-29-3) was virtually ubiquitous. This program was continued to 1976 and indicated that pesticide concentrations were declining.[19] In 1977, the USEPA conducted a one-time sampling event of bivalves from the estuaries previously monitored under the National Pesticide Monitoring Program which demonstrated that the presence of pesticides had continued to decline dramatically.[20]

The Food Safety and Inspection Service (FSIS) of the USDA is responsible for monitoring the residues of chemicals that might be present in meat and poultry products. This responsibility is manifested into the National Residue Program (NRP). The NRP enables the sampling and testing of meat and meat products for residues from pesticides, environmental contaminants and animal drugs.[21,22]

The National Oceanic and Atmospheric Administration (NOAA) created the National Status and Trends (NS&T) Program to assess the effects of human activity on the quality of coastal and estuarine habitats throughout the USA. This program was designed to monitor chemical contamination and the biological effects of chemical contamination. Two efforts were begun in 1984 and 1986 to monitor the tissues of benthic fish (The Benthic Surveillance Program) and bivalve molluscs and sediments (The Mussel Watch Program), respectively. Results and some of the early trends from these programs have been reviewed.[23,24]

A problem arising from the existence of so many monitoring and data gathering programs is the lack of integration of the enormous amount of information that is generated. As a result, policy and decision makers seldom have easy access to this information from which to prioritize research or determine to what extent policy goals are being attained. From this concern, the USEPA has initiated an integrated program for monitoring ecological status and trends known as the Environmental Monitoring and Assessment Program (EMAP).[25] The problem of integrating various sources of environmental monitoring and residue data are even greater when one considers this issue globally.

Outside the USA, there are over 50 international organizations that are involved with pesticides and other pollutants. However, there are legitimate concerns pertaining to the ability of developing nations to possess the resources necessary to evaluate toxicity from contaminated food or perform residue monitoring. As a result, the United Nations has several organizations to address the problems of conflicting agencies and countries with limited resources. A review of these efforts and the problems that exist has been published.[26]

Even with the existence of substantial legislation and monitoring programs enacted to protect the consumer from harmful chemical residues in food, the public remains concerned over the issue. According to a review[27] on dietary pesticide risk assessment, 80% of shoppers surveyed in USA stated that pesticide residues in foods were a major concern. The subject of pesticides and food safety has been reviewed[28] as have residue concerns in seafoods.[29–31]

2.2 Early Analytical Efforts to Respond to Pollution Events

With the introduction of the chlorinated pesticides after the second World War and the general boom in industrial manufacturing and chemical synthesis, pollution of the environment proceeded almost unabated. It was not long before the toxicity of the by-products, wastes and the products themselves to the environment became evident. When the need to analyze for these materials was realized, the technology of the time was the first to be applied to their isolation and analysis. Most of this 1940s and 1950s analytical approach is still in use today. The same can be said of almost all recognized classical and/or official pollutant methods.

Most ''classical'' methods were based on homogenization of the sample matrix with an extracting solvent followed by extensive cleanup procedures to remove, for the most part, lipids and other co-extracting neutral compounds. Water and aqueous homogenate samples were extracted by liquid–liquid partitioning of the pesticides followed by a range of extraction protocols to remove interferences or clean up the sample from emulsions, tissue debris, etc.

Early determinative analyses were often conducted by non-chromatographic methods using measurement of total chlorine content, ultraviolet (UV), visible, and fluorescence spectroscopy. Biochemical techniques that took advantage of the activity of the compound on specific enzyme systems or organisms, such as acetylcholinesterase activity and the survival time of flies exposed to the extracts for certain pesticides were also used.[32]

Such methodologies were most often developed for single compounds. However, as a large number of such compounds became available, the extraction methodology had to become more nonspecific while the analytical methodology had to become more specific. The development of multiresidue methods became a necessity and was fostered by the growing need and concern to monitor for residues in agricultural crops and food animals that were exposed to such compounds. This led to the development of a variety of techniques that were based on different aspects of the nature of the pollutants and the sample matrix to be tested. Many of these procedures, particularly the ''Mills' method''[33,34] for chlorinated pesticides, were subsequently incorporated into what are now ''official'' methods of analysis for these compounds. Nevertheless, these methods have been regularly revised and still adhere to rather antiquated processes for sample homogenization, extraction and cleanup that are labor-, materials- and solvent-intensive. Furthermore, most of these methods have not been adequately examined for method performance in the variety of food-animal species and agricultural products available and must be validated anew for each application.

It became evident that the burgeoning publications of new methods and approaches would have to be centrally controlled and assessed and that particular government agencies should be appointed to control and regulate both the use of the methods and the use and production of these chemicals as potential pollutants. Enter the politicians and the accompanying bureaucrats.

2.3 The Evolution of Analytical Methods into Regulatory Methods

Historically, many of the analyses for residues (whether drugs, pesticides or other environmental contaminants) in biological matrices were generally developed and performed on the basis of individual analytes.[35] It was not until the advent of chromatographic techniques (paper chromatography, thin-layer chromatography, gas chromatography (GC) and high-pressure liquid chromatography (HPLC)) that multiresidue analyses began to be developed and routinely employed. The classical method developed for the analysis of chlorinated pesticide residues in foods using paper chromatography[33] was pivotal in terms of the evolution of multiresidue analyses. The Mills' method, which utilized solvent-partitioning techniques for compound isolation and columns (e.g. Florisil) for fractionation and sample cleanup, became the foundation of the FDA monitoring program for the analytical techniques utilized for multiple-residue analyses.[35]

Further refinement of the Mills' method was published in 1963 using GC and a halogen-specific detector[34] and became known as the MOG (from the authors' last names) method.[35] Subsequent collaborative laboratory studies following the Mills' method led to the publication of multiresidue methods in the Association of Official Analytical Chemists (AOAC) Official Methods of Analysis (1990) and are the basis of most multiresidue methods that are utilized today. A more thorough review of the evolution of these early multiresidue methods has been reported.[36] For example, most methods currently being used by monitoring agencies for pesticide analysis are based on five 'classical' multiresidue methods, some developed over thirty years ago. These methods are commonly called the nonfatty (MOG), fatty (Mills'), Luke, Storherr and Krause methods. Together they detect over 300 pesticides or pesticide-related compounds.[13] Most of these methods have undergone rigorous multilaboratory calibration studies, such as those needed to obtain official acceptance by the AOAC, a requirement in becoming an official method. These methods are the backbone of residue analysis protocols for the FDA,[14] USEPA,[15] and the NOAA.[16] These methods work well under

Table 1 Internet addresses for access to regulatory authorities and/or methods prescribed for environmental analysis

certain conditions and for certain purposes. However, perhaps the greatest drawback to their continued use is their inefficiency as screening methods. Furthermore, these methods are sufficiently complex as to not allow the generation of relevant data in time to prevent contaminated foods from entering the marketplace before a pollution or contamination problem is noted. For example, the FDA is responsible for prohibiting interstate marketing of food containing illegal pesticide residues but, in many cases, food is sold before the FDA completes the analyses.

Table 1 provides the internet addresses of agencies involved in environmental analyses in the USA.

3 METHODS AND THEIR APPLICATIONS

3.1 Sample Preparation

As noted in the beginning of this article, analysis of any sample requires rigorous preparation and consideration of a wide range of factors before proceeding to extraction. These are addressed below.

3.1.1 Documentation

It is of absolute necessity in any analytical undertaking that the analyst provide and be provided with adequate documentation. This process begins with recognition that the data must be generated using validated official methods or their equivalent if the results are to be found acceptable by the environmental analytical community. Detailed protocols for sample collection and identification, chain of custody, transfers, handling, storage, access, etc. exist and are expected to be used in any environmental analytical process. Laboratories conducting such analyses are usually certified and regularly audited to assure that they meet QA and QC guidelines and regulations, of which much is documentation.

3.1.2 Collection

There is a considerable amount of information on sample collection, including statistically derived sampling protocols, in the technical literature.[37–39] Any method of sample collection attempts to ensure that samples represent their populations and that sample sizes are manageable and cost-effective for analysis. Typically, edible aquatic resources (i.e. mainly finfish, shellfish and molluscs) collected for regulatory purposes are either presented whole, as a raw agricultural commodity, or are presented as processed foods (e.g. in canned or breaded form). The same is true of other raw and/or processed commodities.

In conducting sample collection and preparation for analysis the analyst must keep in mind the many possible routes of exposure to the component parts of a target biological sample. The analyst must examine the environment surrounding the target as a whole to fully assess the contribution of air, water, soil, diet, etc. Assurances must be made that a further route of contamination does not occur; contamination by the analyst.

3.1.3 Preservation

Ideally, raw, whole samples should be analyzed directly after collection. Because analysis at the time of collection is often impossible, a few special precautions must be taken to preserve the integrity of the samples. For samples collected for environmental monitoring purposes, the USEPA recommends, for example, wrapping whole fish in aluminum foil and preserving by either icing down samples to be analyzed immediately (i.e. within 24 h) or by quick-freezing in dry ice any samples to be stored (see section 3.1.4).[39]

An alternative method of preservation described in the literature is tissue dehydration. Homogenized molluscan tissues that are first dehydrated with a desiccant mixture (90% Na_2SO_4 and 10% silica) can be wrapped in aluminum foil and held at room temperature for over 15 days without degradation or loss of chlorinated pesticide residues.[40–42] Whatever the biological matrix, consideration for the preservation of the sample itself and the possible pollutants contained therein must be given. Since most of the mechanisms for degradation involve heat, light, air and biological oxidation, enzyme activities and the like, freezing of the sample and wrapping the sample in a clean, non-transparent container will usually suffice to preserve the sample for transport.

3.1.4 Storage

Storage requirements vary according to how quickly residues will be extracted from the tissues. Tissues

to be extracted within 24 h may be stored at normal refrigeration temperatures (+2 to +4 °C); whereas tissues to be held for a longer period of time should be frozen (−12 to −18 °C).[43] Whole fish may be stored for up to six months if kept in a freezer that maintains an even temperature below −26 °C.[39] Samples may be homogenized to decrease storage space. However, if these homogenized samples are to be held for longer than a month, they should be monitored for stability of the pesticide residues of interest.

Storage containers (e.g. zip-lock freezer bags) should prevent contamination, moisture loss or gain, and oxidation, hydrolysis, isomerization, polymerization or other cause of decomposition of tissues or residues. Well-sealed containers are especially important to protect samples from desiccation in self-defrosting freezers.

In addition, samples should be individually packaged for storage to avoid unnecessary handling of tissues not immediately being analyzed. Repeated freezing and thawing disrupts cell membranes. As a result, lipids, and therefore lipophilic pesticides, such as the chlorinated hydrocarbons, may be lost from cells.

The USEPA proposes an alternative method for storing samples, which requires immediate solvent extraction of lipids and pesticides from tissues and then removal of all or most of the solvent. Extracts can then be stored at low temperatures. However, the USEPA recommends evaluating residue decomposition in this state by creating and storing spiked controls along with the sample extracts.[39]

Depending on the nature of the biological sample and the compound being targeted for analysis, different storage conditions may be required. It is of value to conduct storage stability analyses in complement to any analytical procedure. Fortification of control tissues with a range of concentrations of the target analyte(s) assayed over times that are relevant to the storage of actual samples provides the analyst with data concerning the accuracy of the final result. It cannot be assumed that simple freezing of a sample will assure stability, as many compounds will continue to degrade even when frozen at −80 °C.

3.1.5 Shipment

Samples for environmental analyses are often collected under field conditions that do not permit immediate freezing. Nevertheless, samples should be shipped frozen as described above. Samples subjected to elevated temperatures that may exist during travel could undergo rapid degradation. Such degradation may affect the chemical nature of the residues and will definitely affect lipid structure and content of tissues, possibly resulting in a loss of the residues. Changes in structure and content of samples may also adversely affect subsequent isolation procedures.

3.1.6 Stability

In general, most of the chlorinated pesticides and other compounds of interest, such as PCBs and PAHs, present in biological samples occur as relatively stable residues. For example, most DDT has been metabolized or has decomposed to 1,1-dichloro-2,2-bis[*p*-chlorophenyl]ethylene (DDE) (CAS 72-55-9) and 1,1-dichloro-2,2-bis[*p*-chlorophenyl]ethane (DDD) (CAS 72-54-8), both very stable compounds and hence, persistent residues. Most of the 16 chlorinated hydrocarbon pesticides that are regularly monitored by the USEPA have been banned for many years in the USA so are generally found in tissues as their most stable metabolite or decomposition product. Other examples include aldrin (CAS 309-00-2) and heptachlor (CAS 76-44-8), which occur as dieldrin (CAS 60-57-1) and heptachlor epoxide (CAS 1024-57-3), respectively, in tissues.[44]

Standards of all chlorinated pesticides are necessary for residue determination and confirmation. The FDA Pesticide Analytical Manual (PAM) states that these compounds are ''rather stable'' and not subject to decomposition in solution.[45] In a study to determine stability of several of these compounds (individually prepared in 2,2,4-trimethylpentane), results of GC analysis indicated no other substances other than the parent pesticides over a period of eight months. However, the manual recommends protecting all standards from UV radiation. Different recommendations will hold for the other classes of pollutants and individual compounds.

3.1.7 Processing Before Extraction

Samples generally must undergo some sort of processing procedure before the residues can be extracted. Most processing procedures are steps taken to isolate specific organs or tissue types. For some of the environmental monitoring protocols reviewed in the literature,[46] processing includes removal of any tissue parts having direct contact with the aluminum foil or container in which the samples were stored. This step is thought necessary to prevent surface contamination of tissues.

For example, the FDA PAM includes instructions for preparing the edible portion of fresh hard shell and soft shell crabs; oysters; clams; fish; and shrimp, crayfish and other shellfish:[45]

1. For hard shell crabs, a 'homogenous mixture of meat and fatty materials' is examined. This mixture is isolated by heating the crab in boiling water or steaming autoclave for one minute. The claws and other appendages are removed; meat is recovered

from them. After the back shell is removed, all meat from this location is conserved, but viscera and gills are discarded. The entire body of a soft shell crab is used for its analysis.

2. For oysters and clams, a homogenous mixture of meats and liquor is examined.
3. For fish, the following parts are discarded: heads, scales, tails, fins, guts, and inedible bones. Skin remains, and all muscle is filleted for inclusion in the sample. Muscle from very large fish may be sampled from various anatomical locations.
4. For shrimp, crayfish and other shellfish, only the edible meat is examined. All heads, tails and shells are discarded. The manual does not specify what to do with hepatopancreas ('backfat'), which is considered to be edible in crayfish and is often included in processed packages of frozen crayfish tail meat sold in commercial markets.

Homogenizing entire organisms or first isolating the edible portions before homogenizing is very time-consuming and labor-intensive. In most cases, large (20–50 g) subsamples of these materials are used for extraction with only a portion of the extract actually being used in the final steps of analysis. New methods efficient enough to extract and quantify the amount of residue present in a small aliquot of muscle, liver, fat or other relevant biological component could be easily adapted to these procedures and could eliminate some of these inconvenient steps.

3.1.8 Quality Assurance and Quality Control

Analytical data concerning pollutant residues must be easily interpretable, unambiguous, valid and reliable in order to support the decisions made by a regulatory agency to condemn contaminated products or consider assigning an area a designation as a public health hazard. Ideally, contaminated products intended for consumption are condemned and removed before they enter commercial markets in order to limit the amounts of chemical residues entering the food supply. The presence of chlorinated hydrocarbon pesticide residues in edible aquatic species, for example, continues to cause concern because of the as yet unknown health effects of many of these chemicals. Many of the chemicals are classified as suspected carcinogens.[47]

In order to obtain acceptable data, regulatory agencies on both state and federal levels that are currently involved in environmental monitoring must use one of the few 'approved' methods for residue analysis. These are the methods that have undergone the rigorous multi-laboratory calibration studies necessary to achieve the AOAC Official Method status. The methods in the FDA PAM are mostly AOAC approved and designated as such in the manual.[45] Often funds are not available for developing and testing new methods even though the existing methods often fail to be simple, rapid, safe to workers and cost-effective.

For its environmental monitoring programs, the USEPA has an interlaboratory QA program which functions for state and private laboratories working under contract for either the United States Department of Health and Human Services or the USEPA.[39] The program requires all participants to periodically analyze "check samples", samples prepared by a coordinating laboratory with an undisclosed level of residue, in order to "assess the continuing capability and relative performance" of the participant.[39] In addition, the program provides certain nonprofit laboratories with analytical-grade pesticide reference standards. All laboratories must follow the standard analytical methods in the USEPA manual[43] and use standard materials supplied by the USEPA. On-the-job training and assistance may be provided. The USEPA also runs an electronic facility for maintenance of laboratory instruments. The USEPA also utilizes a Laboratory Data Integrity Branch (LDIB) which is responsible for implementation and refinement of the agency's GLPs compliance monitoring program.

Part of the QA of such studies is the use of primary reference standards. Primary reference standards are analytical-grade standards that are greater than or equal to 99% pure. There are several commercial sources for primary standards of the chlorinated pesticides. The standards maintained by the USEPA QA Program are no longer available free of charge to any laboratory that requests them. The USEPA standards are now only supplied to specific laboratories.

3.2 Extraction and Cleanup

This section will provide an overview of the evolution of extraction and cleanup techniques in environmental analysis of biological samples. Table 2[48–50] is a descriptive outline of cleanup techniques. The outline is based on reviews by Walters[48] and Lott and Barker[30] on cleanup techniques for pesticides in fatty foods. The dates in the outline generally correspond to when particular techniques were first developed for cleanup of tissue extracts for pesticide analysis. Most of the techniques have been applied to clean up tissue extracts for subsequent isolation of chlorinated pesticides.

The initial approaches involved standard countercurrent, liquid–liquid extraction. These processes were complicated by the formation of emulsions, requiring lengthy procedures and addition of salts, etc., to prevent or resolve their formation. These extraction procedures also resulted in isolating both the lipophilic pollutants

Table 2 Descriptive outline of cleanup techniques used in methods for pesticide analysis of fatty foods

EARLY

I. Liquid–liquid partitioning
A. Hexane and ACN
1. Hexane – lipids, nonpolar constituents
2. ACN – pesticides, polar constituents
B. Petroleum ether (pet. ether) and ACN

II. Adsorption chromatography late 1950s
- All of the agents act as polar sorbents and retain polar lipids when organic solvents of lower polarity are used to elute analytes.
- used as an adjunct to liquid–liquid partitioning
- applications of alumina and silica gel studied more intensively in Europe

A. Magnesia
B. Florisil (synthetic magnesium silicate)
C. Alumina
D. Silica gel

III. Saponification late 1950s
- used as an adjunct to adsorption chromatography
- limited in use to analytes that are stable to the treatment (e.g. some OCs, such as PCBs, and DDT analogs)

A. Potassium hydroxide–alcohol treatment and subsequent partitioning of analytes into pet. ether
B. Sulfuric acid digestion when working with acid-stable pesticides

LATER

IV. Sweep co-distillation 1960s
- popular in Australia
- UNITREX is a commercial instrument
- can be used to isolate OCs
- OCs in beef fat[26]

A. Technique is volatilization of pesticides in fractionation tube and their subsequent collection in a Florisil trap
B. Relatively non-volatile lipids do not exit fractionation tube
C. Pesticides then eluted from trap and concentrated

V. Low-temperature precipitation[27] −78 °C dry ice/methanol bath
A. Lipids, waxes, H_2O – frozen out of solution (precipitation)
B. Pesticides (polar and apolar) left in supernatant acetone/benzene extraction solvent

VI. GPC 1970s
- official method in Germany
- commercial system available
- often requires additional cleanup with Florisil adsorption chromatography
- widely applicable (fish, OCs)

A. Polymer beads retain small pesticide molecules (M_r 200–400).
B. Lipids eluted from column first (M_r 600–1500)

VII. Semipreparative LC 1980s
- OCs and OPs

A. Uniform microparticulates:
1. Silica (normal phase)
2. ODS-bonded silica (reverse-phase)
   a. ODS-bonded silica retains long-chain lipids
   b. ACN is a common eluting solvent for pesticides

B. SPE cartridges

MORE RECENT

VIII. SFE
IX. MSPD
X. MAE
XI. ASE
XII. SPE
XIII. SPME

ACN, acetonitrile; ASE, accelerated solvent extraction; GPC, gel permeation chromatography; LC, liquid chromatography; MSPD, matrix solid-phase dispersion; MAE, microwave-assisted extraction; ODS, octadecylsilyl; OCs, organochlorine compounds; OPs, organophosphorus compounds; SPME, solid-phase microextraction; SFE, supercritical-fluid extraction.

and all the lipids of the sample simultaneously with little or no resolution. The introduction of sorbent materials such as Florisil and alumina that had a greater affinity for lipids over the relatively more polar analytes was a great advance in the field and greatly simplified the process of pesticide isolation from fatty samples. Removal of fats by saponification enjoyed a brief consideration but many of the pesticides were not stable to the conditions required. Steam distillation and sweep co-distillation which employed sweeping the distillate with a gas to carry the vapor into a collection tube was also found to be applicable but limited. The development of GPC greatly enhanced the ability to perform purification of biological samples for the isolation of pollutants. The procedure is discussed in detail later in this article. The evolution of other chromatographic methods, particularly SPE, also greatly enhanced the ability to perform environmental analyses in biological samples by providing more consistent materials for chromatography. The development of bonded phases that permitted a higher-resolution fractionation of extracts using a variety of phases and solvents was an immediate boon to the field. More recent developments, which will be discussed individually, are SFE, MAE, ASE, new SPE materials and devices, SPME and MSPD.

For illustrative purposes, Tables 3, 4 and 5 are outlines of the methods currently used by the FDA,[45] USEPA,[43] and NOAA,[51] respectively. These methods are very similar; extraction of lipids is done with solvents, lipids are removed by liquid–liquid partitioning and adsorption chromatography with Florisil, and further cleanup and fractionation of pesticide residues is usually performed with additional adsorption chromatography columns. The methods also include supplemental cleanup steps.

As mentioned previously, most analytical methods can be divided into four basic procedures: extraction of lipids and associated pesticides, preliminary cleanup of extract (bulk removal of lipids), isolation of pesticides and detection of pesticides. The separation of cleanup and isolation techniques into two different categories is not always applicable to a method. Some of the techniques, such as liquid–solid adsorption chromatography techniques, have been relied upon to both clean up and fractionate extracts with one elution.

As the preceding information indicates, there is sufficient methodological data concerning the analysis of edible aquatic species for chlorinated pesticides to formulate an opinion concerning their appropriateness and use in developing new or future directions for the field. As underscored by the General Accounting Office report of 1986,[52] there is an existing need to dramatically increase the numbers and types of samples analyzed for chlorinated pesticides as well as other compounds in the environment. A governmental monitoring program for aquacultured and wild-caught species is also proposed for the USA and is already under way in a number of other nations. Both of these needs will foster a demand for new multiresidue methodologies that are capable of handling the expected sample load and that will do so in a cost-efficient and rapid manner.

The ''official'' methods presented here are based on classical techniques that have evolved through and withstood the test of time and use. Methods become classical for a reason. They work. However, these methods are not capable of analyzing an order of magnitude or more samples without producing greatly increased costs for testing and a laboratory gridlock in the effort to impose such lengthy, labor-intensive methods on a task that requires speed and reduced costs. Nevertheless, such ''validated'' methodology has its place in the determinative or quantitative phase of pesticide analysis and in the final confirmation of results that will be taken before a court or regulatory body. The greatest failure is their use as a screening technique, for which they continue to be used today. These methods are not sufficiently fast to provide data on a time line that includes the prevention of contaminated foods from entering the marketplace. Presently, results are obtained after the fact and penalties are levied after the 'damage' has been done to the consumer. Further, these methods require large volumes of solvents, many of which are of greater environmental concern than the compounds they are used to isolate. Much of this solvent is evaporated into the atmosphere, contaminating the air, or may be improperly disposed of, leading to further contamination of aquifers and aquatic habits and resources. One of the greatest costs in analysis today, other than employee costs, is the purchase price and subsequent disposal costs of organic solvents and wastes. In many cases the disposal costs of a given solvent per liter now exceeds the original purchase price. For these reasons alone the use of these ''official'' methods should be severely curtailed and phased out as new ''official'' methods are developed and validated and as new methodology for the screening of samples begins to be developed and implemented. Chemists should avoid developing methods that simply mimic these classical approaches.

Most of the information for the variety of species examined to date involves the use of ''classical'' or modified classical methodology. There have been recent advances in the field, however, that offer a degree of optimism concerning our ability to address these analytical problems.

Table 3 Outline of the methods used by FDA for analysis of chlorinated pesticide residues in fish

I. Extraction of fats (AOAC)
   A. Sample: 25–50 g homogenized fish (approx. 3 g fat)
   B. Homogenization of tissues with anhydrous Na_2SO_4 which:
      • combines with water
      • disintegrates sample
   C. Multiple extractions with petroleum ether (pet. ether)
   D. Cleanup of extracts and rinses with a column of Na_2SO_4
   E. Concentration (Kuderna–Danish concentrator)
   F. Lipid determination
      Note: Fish containing <10% fat may be analyzed by methods for nonfatty foods.
      Total volume of solvent used: approximately 500 mL

II. Extraction of pesticides from isolated fat and oil (AOAC)
   A. Pet. ether/ACN partitioning
      Total volume of solvent used: approximately 365 mL
   B. Florisil column
   1. Florisil and Na_2SO_4 in column
   2. 6% ethyl ether/pet. ether
   3. 15% ethyl ether/pet. ether
   4. Concentration of each eluate
      Total volume of solvent used: approximately 460 mL

      Optional or alternative methods:

   C. ACN/pet. ether backwash (optional – to improve cleanup)
      Total volume of solvent used: approximately 275 mL
   D. Partition chromatography (alternative to pet. ether/ACN partitioning)
   1. Florisil column
      a. Sample
      b. 10% H_2O/ACN
   2. Separator
      a. Eluate
      b. Pet. ether
      c. Saturated NaCl
      d. H_2O
   3. Anhydrous Na_2SO_4
   4. Kuderna–Danish concentrator
      Total volume of solvent used: approximately 181 mL

III. Supplemental cleanup
   A. 6% eluate
   1. +/− GLC or thin-layer chromatography without further cleanup
   2. +/− Second Florisil column (AOAC)

      Total volume of solvent used: approximately 460 mL
   3. +/− Acid–Celite column (AOAC: DDT only)

      Total volume of solvent used: approximately 85 mL (more if sample contains more fat)
   B. 15% eluate
   1. +/− MgO–Celite (AOAC)

      Total volume of solvent used: approximately 140 mL
   2. +/− Alkaline hydrolysis (AOAC)

      Total volume of solvent used: approximately 50 mL
   3. +/− Alkaline hydrolysis followed by MgO–Celite

IV. Determination
   A. GLC/electron capture detector
   B. Confirmation:
   1. Initial test: thin-layer chromatography
   2. Others

Table 4 Outline of the methods used by the USEPA for analysis of chlorinated pesticide residues in human and environmental samples

I.	Extraction of fats
	A. Sample: 5 g
	B. Dry maceration with sand and anhydrous Na_2SO_4
	C. Addition of aldrin as a quantitative recovery check
	D. Multiple extractions with petroleum ether (pet. ether)
	E. Evaporation to dryness for lipid determination
	Total volume of solvent used: approximately 160 mL
II.	Liquid–liquid partitioning
	Pesticide residues are extracted from the fat with ACN and then partitioned back into pet. ether by aqueous dilution of the ACN extract.
	A. Solvents: ACN, 2% NaCl, pet. ether
	B. Drying with anhydrous Na_2SO_4
	C. Concentration (Kuderna–Danish concentrator)
	Total volume of solvent used: approximately 365 mL
III.	Florisil fractionation
	A. Florisil and anhydrous Na_2SO_4 in column
	B. 6% diethyl ether/pet. ether
	C. 15% diethyl ether/pet. ether (with addition of aldrin to this fraction) +/− MgO–Celite column chromatography afterwards
	D. Concentration of each eluate
	Total volume of solvent used: approximately 461 mL (MgO–Celite chromatography would require an additional 140 mL of solvent.)
IV.	GLC/electron capture detector determination

Table 5 Outline of the methods used by the NOAA for analysis of chlorinated pesticide residues in tissues

I.	Extraction
	A. Sample: 3 g
	B. Homogenization with internal standards and Na_2SO_4 and 3 extractions with DCM
	C. Centrifugation (repeated 3 times in conjunction with the extractions)
	D. Concentration with boiling chips
	Total volume of solvent used: approximately 80 mL
II.	Silica gel/alumina column chromatography
	A. Alumina, silica gel and sand in column
	B. Pentane
	C. 50% DCM/pentane
	D. Concentration of each eluate
	Total volume of solvent used: approximately 246 mL
III.	Sephadex LH-20 Chromatography
	A. Second fraction only (50% DCM/pentane)
	B. Concentration of eluate
	Total volume of solvent used: approximately 235 mL
IV.	Determination
	A. GLC/electron capture detector
	B. GLC/mass spectrometric detector confirmation

DCM, dichloromethane.

4 NEW APPROACHES TO SAMPLE PREPARATION AND CLEANUP FOR ENVIRONMENTAL ANALYSES

4.1 Gel Permeation Chromatography

A property of solids can be the presence of holes or pores in the surface, part of the very structure of the materials, that permit penetration or permeation of certain size molecules while excluding others. Thus, this size exclusion or permeation process can be used to fractionate materials by size, using smaller pores to trap or retard smaller molecules and increasingly larger pores to retain or slow increasingly larger, higher-molecular weight-species. Such materials can be said to possess molecular-weight 'cut-offs', retaining molecules below the stated value while permitting the elution of species above this value, acting, essentially, as molecular sieves. This process is not highly specific, however, and lacks resolving power, with overlap of a variety of similar molecular-weight species and, of course, much greater molecular-weight species. Nonetheless, as an approach to roughly separating lower- (such as pesticides and herbicides, MW range of 200–400 amu) and higher- (proteins, carbohydrates, triglycerides, etc. MW range of 600 or greater) molecular-weight species it can often prove to be a useful and powerful technique. This application has been enhanced by the development of automated systems.

Both natural and manufactured materials of defined pore sizes are available. These materials have the appearance of gels when in the presence of solvent, and the process has been given the general name of GPC. These gels are, as might be expected, subject to damage by high pressure and one must be careful to match the permeation material with the appropriate solvent. Newer materials are available for use with higher pressures and are beginning to incorporate surface chemistries that provide a further level of interaction with matrix and target analyte components that enhances the technique for certain applications. The most common materials employed are divinylbenzene-linked polystyrene beads of a 200–400 mesh size.

GPC, especially with the development of automated systems, has found renewed use for the fractionation and cleanup of biological samples for environmental analyses. It has also been used as an adjunct to the extraction and cleanup of samples following isolation of the target analytes by SFE as well as accelerated solvent and MAE techniques. Fractionation of target analytes from the large lipid band from high-fat samples is not always completely successful and additional cleanup steps are often required. These usually involve adsorptive or bonded-phase SPE techniques. Table 6 offers a list of applications and reviews for GPC in environmental analyses.[53–66]

Table 6 Applications of GPC to environmental analysis of biological samples

Analyte	Matrix	Ref.

4.2 Supercritical-fluid Extraction

If gases are maintained at specific conditions of pressure and temperature they will exist in a state known as the supercritical (SC) phase. Under these conditions the gases exist as liquids and can be used in the same manner as other solvents. Since most gases are nonpolar in character, the SC gas can be used as a nonpolar solvent to extract nonpolar analytes from samples. Removing the SC conditions, such as lowering the pressure or raising the temperature, causes the gas to return to its original state. Thus, if we use carbon dioxide (CO_2) from the atmosphere, compress it to a SC state and use it as an elution solvent to isolate compounds from a sample matrix, we can eventually ''dispose'' of this solvent by letting it go back whence it came. Modification of the polarity of the SC gas to obtain a better or more selective extraction can be accomplished with the addition of other gases or, more commonly, the addition of small amounts of ''normal'' solvents, such as methanol, to the SC phase. This provides a high degree of flexibility and more selectivity to the technique. Extraction efficiency in SFE also varies with temperature, pressure, SC fluid flow rate, extraction vessel dimensions, sample water content and a variety of other condition variables.

With the SFE technique carbon dioxide (SC-CO_2) is commonly used as the extraction medium in place of organic solvents. Chlorinated pesticides and associated lipids are soluble in SC-CO_2. They can be extracted from tissues and then collected once the pressurized CO_2 is brought back to atmospheric pressure. This may be accomplished by collection of the SC gas in a solvent or trapping of the analytes by passing the eluate through a solid surface support material. The main advantage of this

technique is that expensive, flammable, and potentially hazardous organic solvents are not used in quantity. However, because the extracts contain contaminating lipids, a cleanup step is usually needed before samples can be injected onto a GC apparatus. Cleanup can be performed with a variety of chromatographic techniques, such as GPC or adsorption chromatography with Florisil, for example.

Water in the sample can interfere with the extraction process and variable water content from sample to sample can confound analytical results. This problem has been overcome with the development of a protocol that calls for first mixing samples with diatomaceous earth and other dessicants (silica, for example) before extracting with SC-CO_2.[67] This step disperses the sample material and allows adsorption of water before extraction with SC-CO_2 or other suitable SC-solvent.

A drawback to the use of SFE is the initial capital outlay required for the equipment and the limits on the number of samples that can be processed in a batch. Newer equipment is becoming less expensive and more efficient for sample throughput and such concerns must be balanced against the savings incurred from not having to purchase and dispose of large volumes of organic solvents.

Table 7 is a list of applications of SFE to isolation of pollutants from biological samples.[62,68–91] An excellent general review of SFE has also been published.[92]

4.3 Accelerated Solvent Extraction

The chemist can increase the rate of interaction of one molecule with another by increasing temperature which is, after all, a measure of relative motion. This increased motion in a closed system results in increased pressure. Thus, if we place a sample in contact with an extracting solvent in a closed system and elevate the temperature and the pressure, we will obtain a greater degree of interaction of the solvent with the sample. This process may translate into more efficient extractions, requiring less solvent and time. This is the case and such procedures have been applied in the form of automated systems performing what has come to be known as ASE. This is also a drawback to ASE; the initial outlay of funds to purchase the equipment. The analyst must assess such cost-effectiveness against sample load, solvent costs, employee costs and savings and turnaround time.

References for the use of ASE on biological samples specifically are limited at this writing. Obana et al.[93] have, however, reported the isolation of up to 19 organophosphorus pesticides at 0.1 ppm or less from four different foods using an ASE instrument operating at 100 °C and 1500 psi in less than 20 minutes. As in SFE, samples were mixed with a drying agent prior to ASE and the extract was cleaned up using GPC prior to instrumental analysis.

4.4 Microwave-assisted Extraction

Microwave heating for sample dissolution in elemental analysis has been a recognized technique for over two decades. The application of microwave irradiation to the extraction of compounds from biological samples has been a more recent development. In general, samples are homogenized and mixed with a solvent and the suspension irradiated at greater than 2000 MHz for short periods of time. Heating is usually repeated several times with periods of cooling in between to prevent boiling. The efficiencies seen with this technique approach those of classical Soxhlet extraction but can be performed much more rapidly. Further modifications of the technique mimic sweep co-distillation or steam distillation with air sweeping the surface of the heated sample and being collected by a condenser that protrudes through the oven housing.Techniques have also been developed using

closed-system microwave heating. The major advantages of MAE are shorter extraction times and reduced solvent use.[94] Ganzler et al.[95] have reported the extraction of a variety of compounds from seed, foods and feeds, finding the process to be more efficient than classical Soxhlet or liquid–liquid partioning extraction. Ren and Desmarchelier[96] applied the technique to the isolation of fumigants from grain, releasing the fumigants into a sealed-system headspace by microwave heating and assaying the headspace. The technique has also found application in the isolation of biomolecules[97] and in conducting environmental analyses in soils, sludge and other non-biological matrices.

4.5 Solid-phase Extraction

The use of the inherent chemistry of the surface of particulates such as silica, Florisil, sodium sulfate, etc. to interact with and assist with the isolation and purification of a variety of pollutants in different matrices, or the process of SPE, has been the backbone of many of the classical methods for performing environmental analyses on biological samples. In the SPE process, a compound is isolated from a liquid sample based on its relative solubility in the liquid mobile phase compared to its solubility in a solid support or a modified solid-support/bound-liquid stationary phase of differing polarity. Isolation is accomplished by passing the analyte dissolved in solvent (organic or aqueous) through a column containing the stationary phase with subsequent elution using an appropriate solvent. Several SPE methods have been developed to facilitate the extraction and cleanup of biological liquid and tissue samples.

For liquid matrices, such as blood plasma or serum, acceptable residue recovery may be obtained using protein precipitation and direct injection without cleanup, but the many impurities present can affect the chromatogram and accumulate on the analytic column, thus resulting in increasing back pressure. SPE cleanup helps avoid these problems and works well with biological fluids such as plasma, urine and cerebral spinal fluid. In addition, SPE extraction and analysis can be automated and done on-line and/or with on-line dialysis and column switching.

Before SPE can be used with solid tissue (e.g. muscle and liver), a separate homogenization step and often multiple filtration, sonication, centrifugation and liquid–liquid cleanup steps are required. While SPE may improve cleanup of these solid tissue samples, the additional labor and materials costs make SPE less suitable, in some cases.

SPE methods published for solid biological samples are often combinations of SPE with other methods such as homogenization, liquid–liquid partition, filtration, sonication and centrifugation. Because choice of SPE column depends on the matrix and on the particular compound of interest, a wide range of solid-phase columns of differing polarities have been used for extraction in biological samples and include C_2, C_8, C_{18}, NH_2, amberlite resins, and polystyrene–divinylbenzene polymers as well as materials that constitute the category of materials for adsorption chromatography.

4.5.1 Adsorption Mode

This mode of solid-phase interaction relies on the inherent surface chemistry of a given material, the functional groups naturally available on the surface. Materials such as alumina (Al_2O_3), Florisil (an activated magnesium silicate), silica (SiO_2) or silicic acid (silica gel; H_2SiO_3), activated charcoal (carbon), etc. can provide such adsorption surfaces. Florisil is perhaps the most often used sorbent in environmental analyses because of its capacity to adsorb fats. Using solvents of low polarity for elution, relatively nonpolar residues can be isolated with high efficiency. Florisil must be activated, however, by maintaining a certain percentage of water. Variability in this value can lead to erratic results. In many cases Florisil can be replaced by alumina. However, basic alumina will lead to the decomposition of some organophosphates and can be highly retentive of more polar target analytes. The silicas have found less general use but have been employed to perform fractionation of more polar constituents in complex extracts from the less polar components.

Extracted samples in solution may be percolated or passed through columns of such materials to obtain a differential distribution of target analytes from other components between the immobile solid phase and the mobile liquid phase. In this manner, target analytes may be retained on the column while co-extracted interferences pass through or are washed from the column by addition of another volume of the same or different solvent. Conversely, the target analytes may be made to pass through while undesirable compounds are retained. Often one sees both and a bit of overlap.

A number of such materials are also manufactured, often in the form of resins, that possess ionic surface chemistry characteristics. These materials may contain an intrinsic negative charge (sulfate, phosphate, etc.) capable of bonding or exchanging positive-ion-containing species or may contain a positive charged surface (quaternary amines, for example) capable of ionic bonding or exchange with negatively charged compounds. The ability to exchange ions using such surface chemistry, thus leading to greater retention of compounds undergoing such exchange, is useful in isolating and resolving charged species from neutral or weakly ionized compounds.

We should also note here that, especially in food chemistry, a number of solid sorbents have been used

to assist in 'drying' the sample. This is accomplished essentially by adsorbing the water in the sample matrix into a solid material such as diatomaceous earth (silica) or sodium sulfate by blending the materials together. Such an approach is used today to conduct SFE, ASE and Soxhlet extraction of homogenized samples. The adsorptive properties of diatomaceous earth blended with the sample eliminates complications due to the presence of water in such extractions. It also provides a level of interaction of the sample and the target analytes with the surface chemistry of the dessicant. Further, solid materials such as sand (silicates) have been combined with samples to serve as an abrasive, using the materials to assist in the disruption of sample architecture through blending or grinding. These agents also have a surface chemistry which may interact with the sample to varying extents.

The sample matrix itself is always a significant contributor to loss of target analytes owing to electrostatic and/or covalent or ionic interactions, much as occurs in the use of sorbent technology. Indeed, the solid sample matrix is the surface chemistry that the analyst must initially deal with in terms of obtaining efficient isolation of analytes, breaking protein binding or ionic interactions of analytes with matrix components. Homogenization of a sample with solvent, extraction by Soxhlet solvent reflux, etc. are extraction/fractionation processes that are controlled by interactions of the analytes with the sample matrix components, the sample's own surface chemistries. These chemistries are far more complex than simple adsorption, however, and cover the entire range from affinity binding (receptor-bound target analytes) to size exclusion, to adsorption and phase distribution.

4.5.2 Bonded-phase Partition Mode

While the use of solids in the adsorption mode does provide a range of chemistries for a variety of applications it does not always provide sufficiently adequate interactions to resolve very similar chemical entities. Thus, alteration of the surface chemistry by derivatization of the functional groups present on the surface with a variety of chemically unique compounds offers the ability to provide an even greater range of interactions that can be brought to bear on a given analytical problem. Solid materials that are commonly used for such purposes have been silica, with available silanols for derivatization, and synthetic polymers such as polydivinylbenzene or polystyrene, which can be chemically modified or initially formed to provide other functionalities.

The derivatizing agents to be used to prepare such surfaces can be designed so as to provide a range of surface chemistries, highly polar to highly nonpolar, high carbon content, low carbon content, cross-linked, etc. that make such materials applicable to a variety of analytical problems. The covalent bonding of the agent to the solid material provides a phase that is immobile or stationary, one that cannot be readily eluted from the material. Thus, this stationary phase can be used, essentially, as an immobile solvent in which sample components can be partitioned. This provides a mechanism for distribution of analytes and other sample components between this stationary "solvent" and the solvent in which the sample is dissolved and applied to the material, and the solvent subsequently applied to the material in an effort to selectively elute analytes or potential interferences.

4.5.2.1 Normal Phase A polar stationary material (or phase). Application of a sample will lead to retention of polar sample components and analytes while nonpolar species will be readily eluted or will pass through the material without retention. Washing with nonpolar solvents will clean the column of such nonpolar sample components or, depending on whether one seeks retention of target analytes, permit further isolation of nonpolar analytes in the eluate. Removal of retained material will require solvents of increasing polarity and/or the use of changes in pH or ionic strength, depending on the nature of the stationary phase and analyte interactions. Examples of normal-phase materials are underivatized silica, and diol-, cyano- and amine-containing derivatives.

4.5.2.2 Reversed Phase A nonpolar stationary phase. Application of a sample will lead to retention of nonpolar sample components while polar species will be permitted to pass through. Washing the column with more polar solvents will further remove the more polar components while removal of the retained species will require less polar solvents, thus, a reversed condition compared to normal phase. Examples of reversed-phase materials are ethyl, butyl, octadecyl, octyl, cyclohexyl or phenyl derivatives.

4.5.2.3 Ion Pairing A nonpolar stationary phase in the presence of an ion that counters the charge of the ion(s) present on the analyte, thus making it neutral and more interactive with the stationary phase; e.g. using tetraethylammonium ions to counter negatively charged functional groups on a target analyte.

4.5.2.4 Ion Exchange A stationary phase containing ionizable functional groups, ranging from strongly to weakly ionized. Application of a sample containing target analyte cations (positive charges) will cause such compounds to be retained by a stationary phase containing anions (negative charges) and vice versa. The material may be washed with organic or aqueous solutions containing no ions or ions of lower ionic strength that will, thus, not exchange for the ions retained. Retained

compounds are eluted with organic solvents or aqueous solutions containing ions of greater ionic strength than those bound to the stationary phase of the column. Some examples of ion-exchange materials are those derivatized with amino groups that are or can be readily quaternized (triethylaminopropyl (SAX); diethylaminopropyl (DEA)) or species carrying a negative charge (benzenesulfonylpropyl (SCX); sulfonylpropyl (PRS); carboxymethyl (CBA)).

4.5.2.5 Mixed Modes All sorbent materials are capable of exhibiting some or all of the characteristics described above. As previously mentioned, underivatized silanols on silica-based sorbents give the material both an adsorptive character that is associated with a normal phase and the intended character of the existing derivative, whether normal phase, reversed phase, ion pairing or ion exchange. Furthermore, many of the derivatives that are used to provide the more polar functionalities are covalently bonded to the silica surface through a C–H-containing chain that may be 1–8 carbons in length. Thus, molecules may undergo ionic interactions, lipohilic or hydrophobic interactions and/or adsorption to underivatized functional groups on the solid support all at the same time. This depends, of course, on the structure of the analytes and the other myriad matrix components. Interaction of target analytes with retained matrix components which are interacting with the solid support/stationary phase is also part of the consideration of the overall mixed-mode interactions taking place.

In all forms of sorbent technology one seeks to obtain varying degrees of retention and elution for the target analytes and other matrix components relative to one another, to take advantage of the relative selectivity of the sorbent and the method applied. This is under the control of several variables, such as the chemical structure of the analytes, the characteristics of the sorbents, the composition of the sample matrix and the solvent-elution conditions or profile selected. Maximum retention or selectivity for a given analyte occurs when the structure and chemistry of the analyte most closely matches that of the sorbent while all other components are divergent from this condition.

The capacity of the sorbent material, its ability to retain a relative quantity of material per gram or milligram of sorbent, must also be considered. This may range from 1–5% of the mass of sorbent (1–5 mg per 100 mg, for example) but this quantity must also take into consideration the fact that matrix components may also be retained on the column. Retention of large quantities of matrix and analytes can greatly alter the character of a column and the subsequent result. Thus, the greater the selectivity of a column for a given analyte, or the more divergent matrix components are from the analytes, the higher the resolution of components in the final eluate.

In all cases the analyst should keep in mind that a large range of variables and possible compositions of materials (sorbents, solvents, pH conditions, etc.) are available for addressing an extraction/analysis problem through the use of sorbent technology and procedures. Several chemically opposite approaches may ultimately work for a given problem.

SPE has played a major role in the development of methodology for the analysis of pollutants in water, with many of the methods now prescribed by the USEPA involving the use of this technology. Table 8 illustrates many of the applications of this process for the isolation of pollutants from biological samples.[53,58,62,63,83,98–125]

4.6 Solid-phase Microextraction

Miniaturization of sorbent technology and the concomitant decrease in solvent (purchase, exposure, disposal)

has also taken a further giant step with the development of SPME devices. In this technology a fused silica fiber coated with polyacrylate, polydimethylsiloxane, Carbowax or otherwise modified bonded phase (addition of other sorbents) is placed in contact with a liquid sample, exposed to the vapor above a sample (solid, liquid) or placed in the stream of a gaseous sample. In such a manner SPME has been used most frequently to analyze volatile and semi-volatile compounds and may be used to replace purge-and-trap procedures. In relation to food chemistry SPME has proven to be particularly applicable to flavor and aroma analyses. While the technique has yet to be extensively applied to analysis of pollutants in biological samples it does, nonetheless, have great potential for such applications.

SPME is based on a simple principle that applies to all sorbent technologies; the materials in the sample will establish an equilibrium with the solid phase, based on their relative distribution coefficients. This does not require complete extraction of the compounds present but rather a representive sample that can be related to samples of known concentrations. Such samples can be readily quantitated by conducting similar exposures to standards of known concentration. The most interesting aspect of this technology involves the ability to use the exposed fiber as both an extraction and a sample delivery device, using specially designed interfaces to place the fiber in-line for GC or LC desorption or elution of analytes. Phases for SPME are available in a range of polarities and properties for application to analyses of volatile and semivolatile compounds as well as for possible applications to extraction of analytes from liquid samples. However, direct application of the method to biological samples for environmental analyses is, at present, lacking.

One of the limitations of SPME is the low capacity of the fiber and the perturbation of equilibria that can occur in the presence of sample components or analytes at very high concentration versus those of lesser concentration. Dilution of the sample can overcome some of these problems but not all, as limits of detection for trace analytes are compromised.

4.7 Matrix Solid-phase Dispersion

Another technique recently developed and applied to biological samples is MSPD. This technique is basically a simple two-step procedure for the extraction, cleanup, and isolation of pesticide (and other chemical) residues from any type of sample matrix (e.g. whole oyster homogenate, fish muscle, milk, fruits, vegetables, etc.). In general terms, the process involves blending a tissue sample (0.1–1.0 g) with lipophilic polymer-derivatized silica particles (e.g. ODS-derivatized silica (C_{18}), which simultaneously disrupts and disperses the sample. This mixture of C_{18} and tissue becomes part of a potentially multiphasic column that possesses unique chromatographic character. Elution of the MSPD column with a solvent or solvent sequence can provide a high-resolution fractionation of target analytes that can be further purified by simultaneous use of co-columns of Florisil, silica or alumina. The final eluate can, in most cases, be directly analyzed or further concentrated or manipulated to meet the demands of the individual analysis. The extracts obtained from these methods are most often detected by HPLC (in the case with drugs) or gas–liquid chromatography (GLC) with electron capture detection (ECD) or mass spectrometry (MS) (in the case with pesticides). However, they can also be used in immuno- or receptor assays.

Additionally, the MSPD process can be modified for a particular application by

1. a change in the ratio of sample to stationary phase support;
2. use of a different polarity polymer or solid support; and
3. blending of the C_{18}/tissue in the presence of modifiers such as chelators, acids, bases, etc.

MSPD could also be used in conjunction with SFE. The water in biological matrices often interferes with the SFE extraction process and analysts have used samples blended with diatomaceous earth to remove water from the sample. However, blending samples first with polymer-coated silicas, as is done in the MSPD process, would remove water and provide an initial stage of fractionation at the point of elution of the analytes with SC fluid and modifiers.

In most cases, eluate samples obtained after MSPD may be directly analyzed by GC without further cleanup. This technique is rapid, simple and inexpensive because it eliminates supplies and separate steps needed for:

1. sample preparation (e.g. blenders or tissue homogenizers);
2. lipid and pesticide extraction (e.g. large volumes of solvents and filtration steps);
3. extract cleanup and pesticide isolation (e.g. more solvents and perhaps adsorption chromatography); and
4. extract concentration (e.g. N_2 and various types of evaporation apparatus).

Three of its main advantages are that

1. it considerably decreases solvent use compared to the ''official'' methods;
2. it allows for a rapid turnover of samples and hence, access to relevant data on the pesticide residue levels present in the samples; and
3. it is amenable to robotics automation.

Table 9 Applications of MSPD to biological sample extraction and cleanup in environmental analyses

As seen in Table 9, MSPD has been used to provide for the multiresidue analysis of various environmental contaminants in a variety of matrices.[126–138]

5 METHODS FOR THE FUTURE

It should be evident from this discussion that methods development for residue determination should focus on rapid screening tests, multiresidue capabilities, metabolite detection and improved sensitivity. The development and use of determinative methods for isolating the compound(s) of interest from biological samples must be rapid and inexpensive, and not generate large volumes of solvents for disposal. Classical or official isolation methods using homogenization and/or liquid–liquid partitioning of biological samples may be sufficient for some applications, such as the generation of data that will withstand a court challenge, but are poor for screening purposes because they are often lengthy, involve multiple steps and use large volumes of solvents. Such methods should not be used, as they are at present, to screen samples to determine a problem.

Solvent disposal is becoming increasingly expensive and environmentally unsound. Therefore, methods using low solvent volumes are desirable. A main purpose of this article was to present a case for phasing out existing official methods in favor of newer technologies that require less sample, less solvent, less employee time and less cost per sample. Newer techniques such as SC fluid extraction, SPE and MSPD offer alternative isolation strategies. When compared to the classical methods, these new methods greatly reduce labor and solvents costs and improve throughput. There are a few drawbacks to the new methods and more work is needed to further develop SPE, SFE, ASE, MAE, SPME and MSPD for use with the many different types of matrices that may contain residues of chemical contaminants. Nonetheless, these methods show tremendous potential. For example, MSPD, when compared to classical methods, has been estimated to reduce solvent use by approximately 98% and analysis time by 97%. Furthermore, once the MSPD column is prepared, the process of solvent elution, collection and analysis can be automated by the use of robotics. Cost of analysis is decreased because less solvent is needed and fewer laboratory technicians need to undergo training. Safety and environmental protection are increased because less solvent is needed. Finally, data are generated more quickly because of the ease of the process and its potential to be automated. These features of MSPD make it a general and perhaps significantly useful method in designing future residue analysis screening programs.

By reducing the sample size, smaller quantities of solvents are needed and less total lipid and co-eluates are present. However, less total analyte is also present. The advantages are that it requires less manipulation, if any, to cleanup the sample and that the capacities of subsequent SPE or adsorption chromatographic materials are not overwhelmed by the quantities of co-extracting interferences that are therein removed. This allows the final extract to be taken up in a smaller final volume, which compensates for the smaller sample size as compared to classical methods. Given that the regulatory levels for the chlorinated pesticides and many other pollutants are relatively high, the use of a smaller sample does not compromise the analytical result. Similarly, larger sample sizes (10 g) of biological materials have been extracted for chlorinated pesticide analysis by blending with solvent and cleaned up using a sequence of SPE columns to give excellent results.[39] These approaches offer a potentially automatable mechanism for the more rapid extraction of the chlorinated pesticides while simultaneously reducing solvent use, overall costs and data turn around time. The extracts obtained from these methods can be screened by gas–liquid chromatography/electron capture detection (GLC/ECD) or gas–liquid chromatography/mass spectrometry (GLC/MS). However, they could also be used in screening formats based on immuno- or receptor assays.

Biotechnology will be the field that will most greatly advance and revolutionize analytical chemistry in the near future. Theoretically, the chlorinated pesticides could be assayed by molecular probes or enzyme/receptor-based electrodes inserted directly into the sample. However, until such technology is fully available, we may apply the growing field of immunology-based detection and quantitation systems to assist us in solving the problems presently inherent in conducting environmental analysis. As described here, there are

presently several commercially available immunoassay kits for the screening and/or quantitation of some of the chlorinated pesticides, certain herbicides and other pollutants. Others could be developed if the market for them is created. Such technology, coupled with rapid isolation procedures such as MSPD or SPE, would allow the analyst to determine the presence and the relative level of contamination of hundreds of samples in a short time frame, especially in comparison to similar screening conducted for the same number of samples by GLC/ECD, GLC/MS, supercritical-fluid extraction/mass spectrometry (SFE/MS), or other instrumental methods of analysis. However, the reliance on such technology will require a complete understanding of the assay's specificity, sensitivity and susceptibility to false positive and/or false negative results. This is not a trivial task but can be accomplished with the proper conjunction of academic, industry, and regulatory agency input and support. The development of these technologies could also produce immunoaffinity column materials that could be used to provide a solventless extraction system for the overall analysis.

Since there is a large variety of biological samples that will require monitoring, it is unlikely that any one approach will be completely applicable to all environmental analyses. Each will require a degree of modification for a given application. However, it is evident that existing official methods should be phased out in favor of newer technologies that require less sample, less solvent, less employee time, and less cost per sample. This article offers a summary of the existing methodology for the analysis of biological samples for compounds of environmental concern and offers an opinion on the future directions for the field. In this age of environmental concern and the recognition of our environmental difficulties and our culpability in them, it is hoped that this information will serve to further the effort to define and ameliorate our past environmental misdeeds.

ACKNOWLEDGMENTS

The author wishes to acknowledge the many contributions of his graduate students to research on MSPD and its applications and their reviews of the literature related to the content of this article; Dr Patricia Gaunt, Dr Michael Crouch, Dr Calvin Walker and Dr Heidi Lott (deceased). Special acknowledgments are extended to Dr Austin Long, the co-inventor of MSPD during his tenure as a post-doctoral fellow, and to Dr John O'Rangers of the Center for Veterinary Medicine of the US FDA, the agency monitor for the research support awarded to our laboratory and gratefully acknowledged here.

Speciation analysis is a term commonly used to describe the analytical processes of identifying and measuring the different chemical forms of trace elements in the sample. Starting from the mid-1980s, analytical techniques for elemental speciation analysis have been advancing at an accelerated pace owing to the rapid advancement in analytical instrumentation. Such advancement is especially evident in the development of hyphenated techniques, which involve the on-line coupling of a species-specific separation device with an elemental-specific detection system. They are now well accepted as the methods of choice for speciation analysis because of their speed, sensitivity, specificity and resolution. Capillary electrophoresis/inductively coupled plasma mass spectrometry (CE/ICPMS) is one of the newest members of this family of hyphenated techniques which has found increasing applications in speciation analysis in recent years. Until today, chromatography has been the dominant separation technique in hyphenated techniques and the subject has been extensively reviewed. However, literature information on capillary electrophoresis (CE)-based hyphenated techniques is much less available. In this chapter, the current status of CE/ICPMS will be reviewed with emphasis being placed on the interface design, analytical performance and applications of the different versions of the technique in speciation analysis.

1 INTRODUCTION

Trace elements play a key role in the functioning of life on earth. They can be either highly toxic or essential to life depending not only on their total concentration levels, but just as important, also on the particular chemical forms in which they exist in the system. The latter information is of additional significance in environmental studies since, besides biological and toxicological concern, the transport and fate of trace elements in the environment is also highly 'species' dependent.

Speciation analysis is a term commonly used to describe the analytical processes of identifying and measuring the different chemical forms of trace elements in the sample. Starting from the mid-1980s, analytical techniques for elemental speciation analysis have been advancing at an accelerated pace owing to the rapid advancement in analytical instrumentation. Such advancement is especially evident in the development of hyphenated techniques, which involve the on-line coupling of a species-specific separation device with an elemental-specific detection system. They are now well accepted as the methods of choice for speciation analysis because of their speed, sensitivity, specificity and resolution. CE/ICPMS is one of the newest members of this family of hyphenated techniques which has found increasing applications in speciation analysis in recent years. Until today, chromatography has been the dominant separation technique in hyphenated techniques and the subject has been extensively reviewed. However, literature information on CE-based hyphenated techniques is much less available.

In this chapter, we attempt to provide a capsule review of the current development of CE/ICPMS technique. The emphasis will be placed on the interface design, analytical performance and applications of the different versions of the technique in speciation analysis. The principles and

instrumental details of the individual CE and inductively coupled plasma mass spectrometry (ICPMS) instruments themselves will not be covered since the subjects can be readily found in many books or review articles.

2 CAPILLARY ELECTROPHORESIS IN SPECIATION ANALYSIS

The species of principle interest in speciation analysis include organometallic species, biological macromolecules, and organic or inorganic complexes of metals (Pb, Hg, Cr, Cu) or non-C elements (As, Ge, S). In environmental samples, these species are usually present at trace levels in highly complex matrices. For such analysis, the use of hyphenated techniques in an on-line fashion is preferred because the closed systems employed minimize the risk of contamination and losses of analysts during analysis. Among the variety of hyphenated techniques developed, the coupling of chromatography-based separation with atomic spectrometric detection are the most widely used ones.

Chromatography in its various forms including gas chromatography (GC), ion chromatography (IC) or high-performance liquid chromatography (HPLC) has been used extensively as the separation technique in speciation studies.[1–3] In chromatographic separation, however, the stationary phases often interact with the analytes, resulting in the alteration of the original distribution of species in the sample. This problem is especially serious in the speciation of inorganic, metal-containing analytes because most of them are not amenable to chromatographic columns. In CE, the electrophoretic separation is applied in free solutions. There is minimum interaction of the analytes with the capillary wall or the stationary phases, since the separation capillaries are mostly made of inert fused silica tubing. Thus, the preservation of the original bondings of the species is often achievable with the proper selection of buffer solutions. Since the separation of analytes is carried out in the aqueous phase, it allows the analysis of labile species by direct injection of the sample without prior derivatization, as is often needed in GC or HPLC separations. This is particularly useful for the analysis of aqueous samples since derivatization could result in sample losses due to incomplete reactions or handling.

The separation mechanisms of CE and chromatography are completely different; the two are therefore complementary to each other in speciation applications. The versatility of CE is demonstrated by its ability to separate a wide range of ionic or neutral species including small inorganic cations or anions, organometallic compounds, organic molecules as well as large biological molecules such as peptide and proteins.[4] The ability of CE to analyze large biological molecules is another crucial factor stimulating our interest in CE because the bindings of metals to peptides and protein enzymes in plant, animal and human tissues have important ecotoxicological implications in environmental studies.

The other attractive features of CE are that the technique is straightforward in principle, easy to operate and simple in experimental set-up.[5] In a typical experiment, the components of a mixture are transported through a horizontal capillary tube by applying a high d.c. potential. A buffer-filled capillary is placed between two containers filled with the same buffer. Typically the tubing is fashioned from fused silica or inert polymeric tubing with a length of 50 to 100 cm and an inside diameter of 25 to 100 μm. Platinum foil electrodes in the two buffer vessels are connected to a d.c. power supply capable of developing a potential of 20 to 30 kV. Electroosmotic flow (EOF) occurs in the capillary where the solvents move from the vessel containing the positive electrode to the one containing the negative. The cause of EOF flow is the electric double layer that develops at the silica capillary surface. The fixed negative charges on the capillary surface arise from the dissociation of functional groups on the surface of the capillary. The negative surface charge attracts positive ions from the buffer solution, thus giving a typical double layer structure. The mobile positive ions that ring the interior surface of the capillary tubing are attracted to the negative electrode, carrying with them the solvent molecules. The analytes are separated by their differences in electrophoretic mobility, with the positive species moving towards negative electrode at velocities faster than EOF; while the negative ones moving slower than EOF. The neutral species, which move with the EOF flow, can also be made to separate by the selective addition of surfactants or other modifiers to alter the surface charge of the analytes.[5,6]

Of the different modes of CE separation techniques, CZE (capillary zone electrophoresis) is the most widely used in elemental speciation analysis. Molecular separation in CZE is based on the difference in the electrophoretic mobilities of the species, which is proportional to the charge of the analyte, and inversely proportional to the frictional forces encountered by the analytes during elution. The latter are determined by the hydrodynamic size of the analytes and viscosity of the medium. Solvent properties such as pH, ionic strength, viscosity are all important parameters because they affect the effective charge on the solute; and for large molecules, also their effective hydrodynamic sizes. CZE has been used widely for the separation of inorganic cations, anions as well as organometallic species. Since cations with the same charge and hydrodynamic radius are often inseparable, a weakly complexing ligand can be added to enhance

Table 1 Speciation analysis by CE with conventional ultraviolet/visible (UV/VIS) detectors

Analyte	Operation mode	Capillary (i.d. × effective length)	Buffer solution	Applied voltage	Sample	Reference (Author)
Hg(II), MMHg, MEHg, MPhHg	CZE	75 μm × 45 cm	Cysteine, 100 mM sodium borate (pH 8.35), 10% methanol	15	Mussel	25 (Medina)
MMHg	CZE	75 μm × 56 cm polymide-coated	Cysteine, 200 mM borate buffer (pH 8.11)	15	Tuna mussel	26 (Diaz)
As(III), As(V), Se(IV), Se(VI)		75 μm × 50 cm polyimide-clad	5 mM chomate (pH 10.0), 0.25 mM HTAB	−15	Standard	27 (Vogt)
Gd-DTPA	CZE	50 μm × 50 cm polyimide-clad	25 mM phosphate (pH 6.8), 10% acetonitrile	25	Standard	27 (Vogt)
Cu-BSA, Cu-MYO		25 μm × 20 cm polyimide-coated	0.01 mol L^{-1} phosphate (pH 2.5)	6	Standard	28 (O'Keeffe)
As(III), As(V), DMA, MMA, BzAs	CZE	50 μm × 52 cm	25 mM phosphate (pH 8)	25	Standard	29 (Rocca)
Se(IV), Se(VI), SeCys, SeMet	CZE	50 μm × 63 cm	80 mM phosphate (pH 8.5), 2 mM TTAB	−12	Standard	29 (Rocca)
As(V), MMA, DMA, As(V)	CZE	50 μm × 75 cm	6 mM chromate solution, pH10, NICE-Pak OFM Anion-BT (1 : 40 v/v)	−28	Coal fly ash	30 (Caruso)
As(III), DMA, Se(IV), AS(V)	CZE	75 μm × 50 cm	15 mM phosphate	25	Standard	31 (Schlegel)
Se(VI), AsF6(V), Se(IV), As(V), PhAs, ABAs, DMA	CZE	75 μm × 70 cm	1 mM CTAB, 50 mM CHES, Triton X-100 0.03 wt%, LiOH 20 mM, pH 9.4	−30	Standard	31 (Schlegel)

Fe(II), Fe(III)	CZE	50 μm × 30 cm	100 mM borate, pH 9.2, 10 mM *o*-phenanthroline and EDTA	30	Standard	33 (Schaffer)
Ferrocenecarbozaldehyde, ferrocene, butylferrocene	MEKC	75 μm × 70 cm	10 mM phosphate pH 6.7, 30 mM SDS, 35% acetonitrile	25	Standard	27 (Vogt)
SO_4^{2-}, $S_2O_3^{2-}$, $S_4O_6^{2-}$, HS^-	CZE	75 μm × 60 cm	1.5 mM PM, 10 mM TRIS, 0.5 mM DETA, pH 8.0	−20	Standard	34 (Motellier)
Metallothinoeins	CZE	75 μm × 94 cm polyimide-clad	50 mM Tris-GCl pH 9.1		Rabbit liver	35 (Richards)
Ca- and Zn-binding proteins	CZE	50 μm × 100 cm	100 mM Tris-100 mM tricine (pH 8.3), or 50 mM Tris-384 mM glycine pH 8.3 containing 2 mM $CaCl_2$, $ZnCl_2$ and EDTA	30	Proteins	36 (Kajiwara)
Ca- and Zn-binding proteins	MEKC	50 μm × 100 cm	100 mM Tris-100 mM tricine (pH 8.3), 0.1% SDS	30	Standard	36 (Kajiwara)
Cu, Zn haemeto- and protoporphyrin	MEKC	50 μm × 50 cm	40 mM SDS in CAPS buffer (pH 11)-DMF (10 : 2, v/v)	30	Standard	37 (Kiyohara)
TML, TEL, DPhSe, MphSe	MEKC	50 μm × 44 cm	50 mM SDS and 5 mM β-cyclodextrin in 25 mM phosphate borate buffer, pH 6.0	15	Standard	38 (Ng)
Fe(II)- phenols, tanning agents	CZE	(25–100) μm × (12–100) cm polymer-coated	Borate/HCl (pH 8.5)	12	Beverage	39 (Harms)

DMA, dimethylarsenic acid; MMA, monomethylarsenic acid.

selectivity and separation efficiency.[7,8] Many organic compounds with electron-donating properties can be used as weak charge transfer complexes with metals for such applications. Significant advancement has been made to exploit various chemical techniques of complexation, ion-pairing, and micellization interactions between the metal analytes and electrolyte additives to enhance separation or alter selectivity.[9]

Conventional reversed-phase liquid chromatography (RPLC) ion-pairing reagents, ionic polymers and dicarboxylic acids have all been effectively used to enhance CZE separation. A number of reviews are available discussing the use of CZE for speciation analysis of metals in different oxidation state, organometallic compounds, and metal complexes with different organic or inorganic ligands.[7–15] In these applications, the proper selection of operational electrolytes to control acid–base and complex formation equilibria is the most important in controlling the effective electrophoretic mobilities of the analytes. Such applications are especially useful for the determination of transition metals, heavy metals and rare earth elements.

In addition to cations, CZE has also been used extensively for the separation and speciation of inorganic anions of arsenic, selenium, phosphorus, sulfur, halogen and phosphorus compounds. The mechanisms of anion separation by CE were reviewed by Kaniansky et al.,[13] and Haddad et al.[14] Comparison between CE and RPLC techniques for metal speciations was reviewed by Timerbaev et al.[11] The application of CE for the separation of inorganic metals and organometallic species in environmental samples including air particulates, soils and water samples was discussed in several recent reviews.[16,17] The main emphasis of these reviews was placed on the discussion of matrix effects in complex environmental samples; and the different approaches one can take to minimize such matrix interference.

For the separation of organometallic or uncharged organic or biological molecules, MEKC (micellar electrokinetic chromatography) is the other CE technique commonly used.[18–22] A recent review on the use of micelles as a separation media in both HPLC and CE applications was given by Khaledi.[23] The set-up of the apparatus in MEKC is the same as those of CZE. The chief advantage of MEKC is that both neutral and charged compounds can be separated. Terabe et al.[18] first reported the use of micelles in buffer solutions for CE in 1984. The charged micelles are incorporated in the buffer solution to act as a pseudo-stationary phase. The separation of the analytes is based on the differences in their partition coefficients between the buffer solution and the micelles. Such differences result in the separation of species, which by themselves would have the same electrophoretic mobilities, because of the electrophoretic migration of the micelles along the capillary. Furthermore, with the inclusion of suitable additives in the buffer, unique separation or selectivity may be exploited in MEKC.[20,23]

MEKC has found wide applications for the separation of metal binding proteins, peptides or porphyrins. For the separation of these biopolymers, conditioning or shielding of the fused silica capillary wall is often necessary in order to avoid undesirable wall interactions of the analytes. Two approaches can be taken. The first is to apply dynamic coatings, with deactivator compounds added in the solution to continuously condition the capillary during separation. Alternatively, a permanently coated or organic polymeric capillaries can be used to replace the fused silica capillary commonly used.[24]

The application of CE for speciation studies started to grow rapidly in the early 1990s. Most of these studies used on-line spectrophotometric or fluorescence detectors. Limited by detection sensitivity, this earlier work involved primarily the analysis of standard solutions or samples with higher metal concentrations. Table 1 lists selectively some of these reports to illustrate the range of application of CE techniques. The primary CE modes used in these studies were CZE and MEKC. All the listed studies were based on CE with UV/VIS detectors except the one by Schlegel, in which conductivity detector was used. The operating conditions, buffer systems used for each of these studies are included in the table along with sample and analysts information. The versatility of CE separation can be seen from its wide applicability in systems consisting of a variety of metals, anions and organometellic species in different types of sample matrices. The capability of CE is further enhanced when it is coupled with sensitive and elemental specific detectors such as plasma-based atomic spectrometry or mass spectrometry (MS), as will be discussed in later sections.

3 OPTIMIZATION OF CAPILLARY ELECTROPHORESIS SEPARATION

To achieve high efficiency in CE separation requires the careful control and systematic optimization of the various operating parameters in the system. The injection mode, pH control of the buffer solution, stability of the applied voltage, conductivity and electric current of the buffer system are all important factors contributing to the resolution and reproducibility of the separation.

The type of injection and injection duration are important in CE as it may bias the results and lead to poor separation and irreproducibility of migration times.[40] The two basic sample injection techniques in CE are hydrodynamic injection and electrokinetic injection. The former is to introduce the sample by hydrodynamic flow through hydraulic pressure, while the latter is by

electrophoretic flow with applied d.c. potential. The volume of sample injected is a compromise between separation resolution and sensitivity requirement. Quite often in speciation studies, the concentration-based detection limits in CE have to be maximized through the injection of large sample volumes. However, increasing the injection volume risks the possibility of degradation in resolution because of overloading.

For large sample volumes, using electrokinetic injection will give a better resolution than hydrodynamic injection as the sample is continuously being separated during the entire injection period. Magnuson et al.[41] reported enhanced sensitivity with detection limits in the ppt range for arsenic species of As (III) and As (V) by CE/ICPMS using electrokinetic injection. However, such injection often complicates the quantitation process as the amounts of individual analytes introduced during the sample injection period may vary depending on their respective electrophoretic mobilities and conductivities.[40] Generally speaking, electrokinetic injection is a viable sample introduction technique which is more suitable for the analysis of samples requiring on-line preconcentration. But its precision and accuracy are strongly affected by experimental conditions and thus require tighter control compared with that of hydrodynamic injection.

Reproducible sample injection is crucial to obtain quantitative data in applying CE for speciation studies. Recently, a number of modified CE injection techniques based on flow-injection principles or automated devices have been developed.[42–44] These injectors offer the opportunity for fully automated sample injection with high precision, and thus are preferred for applications involving CE hyphenated techniques for speciation studies.

The conditioning of the surface of the capillary is also important in achieving reproducible CE separation. The pH of the buffer system has a direct impact on the EOF because buffer pH affects the charge of the inner capillary tube surface. This is because the degree of protonation of the silanol groups increases with decreasing pH. Phosphate or other anions commonly used in buffer systems can also reduce EOF through the conversion of acidic silanols on surface to more easily protonated silica–phosphate complexes.[45] Preconditioning of the capillary is therefore important to control the equilibrium of the surface charge.[45,46] The use of CZE for the separation of arsenic species of As (III), As (V), MMA, DMA and arsenilic acid (ANA) was found to depend significantly on capillary preconditioning and pH.[47–49]

The separation efficiency of CE is related greatly to pH and the choice of buffer because they affect the electrophoretic mobility and separation efficiency of the analytes. During separation, charged species migrate in the capillary under the influence of an applied electric field. Ideally, the buffer should not interact chemically with the species of interest, maintain the pH and minimize ion loss. The choice of buffer often involves trade-offs between separation efficiency and peak resolution. In cation analysis, for example, cations with a high charge will be more easily trapped in the electrical double layer than cations with smaller charge. Thus, using a buffer containing a cation with a high charge will reduce analyte cation sample loss caused by trapping in the double layer. On the other hand, the higher charged ions are likely to interact with anionic ligands in the buffer, which affects resolution. The pH of the buffer should also be optimized since selectivity and resolution may occur at different pH range, and thus the two parameters need to be investigated individually.

The choice of buffer and its concentration also determines the conductivity of the solution within the capillary.[50] Conductivity of the sample analytes and electrolytes is a main concern because it will affect the electrophoretic resolution as well as the amount of heat generated in the capillary. When the conductivity of the sample approaches or exceeds that of the electrolytes in the buffer solution, CE resolution is degraded. Increasing the conductivity of the electrolyte solution leads to increased Joule heating which produces peak broadening. On the other hand, if the conductivity of electrolyte is too high, heating may be large enough to increase the temperature of the electrolyte, and produces radial temperature gradients in the capillary. Consequently, convection currents will lead to mixing and the degradation of resolution. If the conductivity is too low, the voltage gradient in the injected sample plug and nearby analyst zone in the capillary will always be smaller than the voltage gradient in the electrolyte solution. As a result, electrophoresis peaks will also be distorted. It is generally recommended that the concentration of the electrolysts should be at least 1000 times the concentration of sample.

Applied voltage is another factor affecting CE separation. As the applied voltage is increased, the separation time is reduced. However, such increase causes an increase in electric current, resulting in Joule heating in the capillary. Consequently, the EOF and electrophoretic mobility of the analytes will also be affected. Thus, while high electric field often improve resolution and efficiency, the effects of Joule heating essentially sets the limit on such increase in real practice. For efficient separation, a stable and reliable electrical current along the capillary is necessary. In addition, the capillary should also be cooled actively during analysis to prevent local heating.

4 DETECTION SYSTEMS FOR CAPILLARY ELECTROPHORESIS

As the total sample intake by CE analysis is extremely low (5–100 nanoliter range), the concentration-based sensitivity of the detection system must be sufficiently high in order to be applicable in speciation analysis. The development of highly sensitive and selective detectors for CE has always been a subject of intense interest. Until today, ultraviolet and fluorescence detectors are the most commonly used ones for CE in speciation analysis. As was shown in Table 1 the detection limits of these detectors are generally in the order of 10^{-5} to 10^{-6} M range. Such sensitivity is not sufficient for the speciation analysis of trace quantities of analytes often faced in environmental samples. Other detection techniques such as MS, laser-induced-fluorescence, amperometry and conductivity have all been successfully applied as CE detectors with high sensitivity.[51–55] However, these detectors lack the needed 'elemental specificity' to selectively detect the specific elemental species of interest in the presence of complex matrix interference.

As was stated earlier, the use of atomic spectrometry as an elemental specific detector in hyphenated techniques has been a popular approach in speciation analysis. Such detection may be single element in nature, e.g. atomic absorption spectroscopy (AAS), or multi-element, e.g. inductively coupled plasma optical emission spectroscopy (ICPOES). The interface of chromatography with these detection devices is relatively straightforward due to the continuous flow characteristics and the compatible flow rates (mL min^{-1} range) of the two partner devices. The early interface problems in these systems have now been mostly alleviated. Most of these interface systems such as high-performance liquid chromatography/inductively coupled plasma atomic emission spectroscopy (HPLC/ICPAES) or gas chromatography/microwave induced plasma (GC/MIP) currently in use are relatively cheap and easy to construct, and can be readily constructed and demounted when not in use. The instrumental design and their applications in speciation analysis have been the subject of many reviews as was given in several articles included in the earlier references.[1–3]

Before the wide availability of ICPMS, inductively coupled plasma atomic emission spectroscopy (ICPAES) was the most popular detection systems used in hyphenated CE techniques. Olesik et al.[56] was the first to report the application of CE/ICPOES for elemental speciation of chromium and iron. The system was shown to be a viable technique for the rapid analysis of free ions of different charge states and organometallic species with sensitivities in the low ppb range. A similar system developed by Lu et al.[57] was applied successfully for the speciation of Cu^{2+}, $Cu(EDTA)_2^{2-}$, and Cr^{3+} and $Cr_2O_7^{2-}$ with sensitivities also in the ppb range. These and other earlier studies provided valuable information on the design of the interface and nebulizer to couple CE with the plasma systems. On the other hand, they also demonstrated clearly that further improvement in detection sensitivity is needed before hyphenated CE techniques can be utilized effectively for routine speciation analysis of real world samples.

ICPMS represents the newest generation of multi-elemental detection instrument. The state-of-the-art of the instrument can be found in many reviews including the more recent ones by Caruso et al.[58,59] Compared to ICPOES, ICPMS is 10–1000 times more sensitive, and offers simpler spectral interpretation with less interference. The analytical capability of MS to monitor ionic species from ICP has been well known since the mid-1980s by the work of Houk et al.[60] Different versions of the instruments are now available commercially. In these instruments, the plasma torch is in a horizontal position under normal pressure. An interface cone is placed between the plasma source and the mass spectrometer. The ions produced in the ICP are transported into the MS through a small hole in the cone through a differentially pumped interface linked to a quadruple spectrometer. Quadruple MS are the most commonly used MS instrument as it is more compact, less expensive and more rugged than magnetic sector MS. The quadruple MS covers a mass range of 3 to 300, with unit mass resolution, and has a dynamic range of 6 orders of magnitude. Over 90% of the elements in the periodic table can be determined by ICPMS with detection limits in the sub-ppb range for most elements. The spectra so produced, which consist of a simple series of isotope peaks, are much simpler compared with conventional ICP emission spectra. These spectra can be used for quantitative measurement based on calibration curves, often with an internal standard. The fast scan rate and peak jumping routines of the quadruple MS result in an essentially simultaneous multi-element detection when it is interfaced on-line to different sample introduction systems.

ICPMS is an unique technique to discriminate between the masses of the different isotopes of an element where more than one stable isotope occurs. Consequently an enriched isotope that normally is present in relatively low abundance can be used as a tracer in metabolic studies to compare to a reference whose abundance is constant. Another major advantage is the application of isotope dilution analysis. Isotope ratio for two selected isotopes of an element of interest is measured in a solution after the addition of a known quantity of a spike that contains enrichment of one of the isotopes,

Figure 1 Schematics showing the components of an ICPMS instrument and its interface to different sample introduction systems.

permitting calculation of the original concentration of the element. The use of isotope dilution saves the time required to obtain calibration graphs and compensates for matrix effects as was illustrated in the recent articles by Heumann et al.[61,62] Using ICPMS coupled with SEC (size exclusion chromatography), these authors were able to determine the extent of complexation of Cu, Mo and Fe with different fractions of dissolved organic materials or humic substances in aqueous samples. The speciation of iodine compounds of iodate, iodide and organoiodine in fresh and seawaters were also successfully accomplished by the coupling of ICPMS with reversed-phase HPLC. The sensitivities of ICPMS detection for these species were down to the pg mL^{-1} range.

Since the late 1980s, a variety of ICPMS based hyphenated techniques have been reported in the literature. Thompson and Houk[63] first reported the use of plasma MS as detector for HPLC for the speciation of As and Se. The study demonstrated the superior capability of ICPMS for multi-element detection and isotope ratio analysis with high precision and accuracy. A variety of sample introduction devices have since been interfaced to ICPMS for speciation applications. Figure 1 gives a schematic representation of the basic components of ICPMS; and the wide variety of sample introduction or chromatographic separation techniques with which ICPMS has been successfully interfaced.

The coupling of CE and ICPMS provides an ideal tool for speciation analysis because it combines the high separation efficiency of CE with high elemental sensitivity and specificity of ICPMS. The analytical performance and instrumentation of the variety of ICPMS-based hyphenated technique can be found in some recent reviews.[64]

Table 2 Attributes of CE and ICPMS

Advantages of CE	Advantages of ICPMS
High efficiency and resolution	High sensitivity
Less sample requirement	Multi-element determination
Ionic and large molecules	Isotope dilution analysis
Less reagents consumption	Wide dynamic range
High separation speed	Less mass spectral interference

Table 2 outlines the major attributes of CE and ICPMS which make the coupling of the two an attractive approach in speciation studies.

5 CAPILLARY ELECTROPHORESIS/ INDUCTIVELY COUPLED PLASMA MASS SPECTROMETRY SYSTEMS

When used as a stand-alone instrument, ICPMS can generally use the same or closely similar sample introduction techniques that had been developed for the more well-established ICPOES systems. Many high efficiency nebulizers have been developed to efficiently transport the liquid samples or chromatographic eluent to the

plasma in aerosol forms so that they can be effectively vaporized, atomized, ionized or excited. However, different sets of problems occur when these interfaces are applied to CE. In the following text, general considerations on the design of the interface will be introduced. Some of the successful interfaces reported in the literature along with their applications will be described. A summary of the different systems studied in these reports is given in Table 3. The types of metal compounds which have been speciated and the corresponding detection limits for each of these species are included in Table 3. Details of these systems will be discussed further in later text.

The technique of CE/ICPMS is still in the early stage of development and thus only limited numbers of papers with experimental details have been published so far. The information summarized in Table 3 is meant to give an overview of the status of development of the technique rather than an exhaustive literature review.

5.1 General Consideration in Interface Design

There are three main challenges in the design of an interface between CE and ICPMS. First, in CE/ICPMS, different from those of conventional CE set-up, the exit end of CE capillary is no longer placed inside a grounded buffer reservoir. Thus, one has to find an alternative way to complete the electric connection in order to apply the high voltage across the entire CE capillary. Secondly, to achieve high concentration-based sensitivity, the transport efficiency of the interface needs to be as high as possible because of the small volumes of samples introduced in CE (5–50 nL). Lastly, along with high transport efficiency, the interface should also be able to minimize electrophoretic band broadening caused by problems of dead volumes or flow incompatibilities. To solve these problems requires a substantial modification of the conventional nebulizer/spray-chamber designs

commonly used for sample introduction in atomic spectrometry. Using these conventional nebulizers, which are built to handle flow rate in the mL min^{-1} range, would not only lower the sensitivity due to sample lose or dilution, but also degrade the electrophoretic peak shape because of dispersion in the laminar flow of the conduits.

Two general approaches have been taken to achieve proper electric connection of the CE capillary in CE/ICPMS. In the first approach, the electric connection to the capillary was made by conducting silver paint on the outside of the capillary. The grounded cathode end is then placed directly into the nebulizer for sample transport to the plasma.[56] The second approach is to mix an electrically conductive sheath buffer flow to combine with the CE flow at the tip of the CE capillary before entering the nebulizer.[57,70] The sheath flow serves two purposes. Besides serving as an electrical connection to the cathodic end of the separation capillary, it also serves as a make-up flow to match the liquid flow requirement of the nebulizer. All the connections and tubings used in these interfaces are micro-volume connectors in order to minimize the dead volume. The operating conditions such as buffer composition, flow compatibility and nebulizer gas flow rate also have to be carefully optimized to obtain satisfactory performance. Interfaces based on the use of sheath flow design have been found to give minimum band broadening with aerosol transport efficiency in the range of 20–80%, depending on the total liquid flow rate delivered to the nebulizer.

Many different new designs of nebulizers for CE interface have been reported in the literature, and these include DIN without the use of a spray chamber, and low-flow versions of concentric nebulizers based on Meinhard concentric nebulizer design coupled with low volume spray chambers. The transport efficiency in general is close to 100% for the direct injection techniques, and better than 50% for the low-flow nebulizers.

Although both CE and ICPMS are now well established techniques by themselves, the coupling of CE with ICPMS is relatively new and interface designs are still being developed and improved. Up to the present, there has not yet been a fully commercialized CE/ICPMS in the market which is of universal utility to all types of analytes of interest. Nevertheless, the use of direct injection nebulization and low-flow nebulizers appears to hold the best potential for routine applications.

5.2 Glass Concentric Nebulizer

Olesik first described the application of CE/ICPOES/MS for elemental speciation.[56,65] A commercial Mainhard concentric nebulizer was modified to couple CE capillary to ICP. The electrophoresis capillary was fitted into the inner tube of the nebulizer. The outside 4–5 cm of the capillary was coated with silver paint, which serves as an electric connection between the solution at the tip of the capillary and the ground. Under some conditions, contamination of the capillary effluent by Ag was observed, especially when ligands capable of complexing strongly with Ag were present in the buffer solution. A close to zero liquid dead volume and up to 100% sample transfer efficiency was obtained with the interface.

Using this interface, a series of Cr and Fe compounds were separated and detected using CE/ICPOES. Satisfactory electrophorograms of a series of separations of tin (Sn^{4+} and Sn^{2+}), strontium (Sr^{2+}), arsenic (As (III) and As (V)) and chromium (Cr (III) and Cr (VI)) species presented each at 1 ppm concentration was reported. The separation of free ions from metal ligand complexes such as the mixture of Cu^{2+}, $Cu(EDTA)_2{}^{2+}$ was also accomplished. The detection limit for Sr using CE/ICPOES with an injection volume of 0.14 μL was 0.3 ppb, compared with 0.03 ppb obtained with direct ICPOES using conventional sample introduction techniques. The interface was also used to couple CE with ICPMS and the detection limits found in these coupled systems were in the range of 0.06–2 ppb for the elements investigated. Detection limits for Sr, Cr, As and Sn by CE/ICPMS were a factor of 6–200 times worse than that of direct ICPMS analysis using standard nebulizers and spray chambers. These initial studies suggested the promising potential of CE/ICPMS technique, but also the need for sensitivity improvement in order to be used for routine speciation analysis of real world samples.

Another version of Meinhard type nebulizer design was developed by Lu et al.[57] The unique feature of this design is the variable positioning of the capillary in the concentric nebulizer. The CE capillary was inserted into the central glass tube of the nebulizer, about 2 cm away from the tip. Another silica capillary was also inserted coaxially into the central tube around the CE capillary. The maximum distance between the end of the CE capillary and the outer tube was 18 mm. A coaxial liquid sheath using 10 mmol L^{-1} NaCl solution was supplied through the outer capillary used to complete the electric circuit of CE. The signal was found to decrease as the make-up sheath flow increases because of sample dilution by the make-up flow.

The system was used for the analysis of metal binding proteins, metallothionein and ferritin. The effect of CE capillary positioning on separation resolution was studied. Because of suction induced by the nebulizer, the farther the capillary was placed inside the nebulizer, the poorer was the resolution. The problem can be overcome by supplying negative pressure to the sample vial, but a compromise has to be made between resolution and signal intensity, which is affected by pressure applications.[57] The detection limits reported were 2.5 μg of $^{57}Fe\ g^{-1}$ and

0.055 μg of $^{114}Cd\,g^{-1}$. The absolute detection limits for 73.6 nL sample injection were 184 fg of ^{57}Fe and 4 fg of ^{114}Cd.

Mei et al.[69] reported a new version of the modified concentric nebulizer interface. The interface used a simple Y quartz tube. The first arm was connected with the outer end of the CE capillary. The second arm was connected with the auxiliary capillary used to draw up the make-up flow. The other end of the auxiliary tubing was dipped into the 0.05 M HNO_3 solution. The third arm was connected directly to the sampling tube of the nebulizer. The solutions were individually sucked up into their respective capillaries by self-aspiration and then mixed in the junction before being aspired into the nebulizer. While the make-up solution was contacting with the ground of the d.c. supply, the buffer electrode solution was connected to the negative polarity of the d.c. supply. The negative high voltage was used to form an opposite EOF against the self-aspirating flow. Because the interface was placed outside and independent of the nebulizer, it is more flexible and could be easily connected to various types of nebulizers. High efficiency separation of Cu^{2+}, $Cu(EDTA)_2^{2-}$, and Cr^{3+} and $Cr_2O_7^{2-}$ pairs was observed.

5.3 Direct Injection Nebulizer

DIN is a micro-concentric pneumatic nebulizer without the use of a spray chamber. Instead, the liquid sample is nebulized directly into the central channel of the plasma torch.[72] A commercial DIN unit is now available in the market. DIN has been used widely as an interface for micro-bore HPLC/ICPMS systems because of its high transport efficiency, low dead volume, and flow compatibility with the chromatographic systems.

Liu and coworkers[73] used a Microneb 2000 DIN nebulizer to interface CE with ICPMS. The CE capillary is inserted concentrically inside the fused-silica DIN sample introduction capillary. A liquid make-up flow in the DIN sample introduction capillary around the CE capillary was used to establish the electric contact. The design has an extremely small internal volume of $<2\,\mu L\,min^{-1}$ and can accommodate low rate in the range of $10–100\,\mu L\,min^{-1}$. Besides serving as the electric contact, the make-up flow design in DIN is also used to ensure that the DIN system could be operated independently of the CE system, and thus independently of the EOF generated by the eletrophoresis process. This is advantageous because it allows the use of different buffers and applied voltages to optimize separation

It was found that the DIN interface did not cause any noticeable suction and back pressure problems during CE analysis. Baseline separation of Li^+, K^+, Sr^{2+} and Tl^+ was achieved in less than 210 s. The detection limits ranged from $7\,pg\,mL^{-1}$ for Tl^+ and $1000\,pg\,mL^{-1}$ for K^+. Satisfactory results were also reported for the speciation analysis of Se and As.

5.4 Ultrasonic Nebulizer

Ultrasonic nebulizers (USN) are used widely in ICPOES to improve transport efficiency and detection capability for elemental analysis. Its improvement over conventional pneumatic nebulizer systems is the dense aerosol and smaller droplet produced, and the resulting 3–8 times improvement in detection limits.[74]

In a series of studies, Lu and Barnes[67] have made a systematic comparison of the efficiency and resolution between USN and conventional concentric nebulizers as an interface in CE/ICPMS. A commercial pneumatic-based USN was used in the study. The USN interface was found to provide considerable improvement in separation resolution and better signal sensitivity. It also showed low sensitivity to mechanical parameters. The systems were used for the separation of metallothioneins. The signal intensity of the USN system showed an improvement of 3.6–8.4 fold compared to those with the concentric nebulizer interface. The gain in sensitivity, however, was compromised by the high background noise. Caruso et al.[75] has recently improved the USN interface design which showed noticeable improvement in resolution and signal/noise ratio.

5.5 Oscillating Capillary Nebulizer

Caruso et al.[76] recently reported the use of a pneumatic-based Oscillating Capillary Nebulizer (OCN) as an interface for CE/ICPMS. One attractive feature of the interface is its compatibility with a wide range of flow rates from $1\,\mu L\,min^{-1}$ to $2\,mL\,min^{-1}$. The transport efficiency was close to 100% under low flow rate conditions. In OCN, the aerosol was generated by both the flow of the nebulizer gas and the induced oscillation of the transport tubes. The concerted action enhanced the breakup of liquid samples into small droplets. The design used by Caruso is a modified version of the original model. The original OCN was constructed from two concentrically mounted flexible fused-silica tubes used each for the liquid and nebulizer gas flows. In the modified version, a three tube system was used and the additional tube was installed to accommodate a makeup buffer flow for ground connection.

Detection limits in the low ppbs were reported for the analysis of both inorganic cations and anions using the system. However, noticeable broadening and tailing of the peaks were also observed. It was suggested that both the turbulence in the spray chamber and the action of nebulizer suction could be responsible for the problems observed.

5.6 Hydride Generation

HG provides a different approach to interface CE with ICPMS.[71,77] It circumvents some of the problems in nebulizer-based interfaces in which the CE buffer often causes the build up of deposits on the sampling interface, and thus influences the long term stability of the system. On the other hand, the gaseous hydride can be nearly quantitatively introduced into the plasma without the problem of high dissolved solids commonly associated with CE buffers. The common problem of chloride interference (m/z of 75) in HG systems can be eliminated by using a microporous membrane as the separator.

The HG system is particularly useful for the speciation of hydride-forming species such as As, as was demonstrated in the work by Mathew et al.[77] In their system, the CE unit is interfaced to a microporous membrane as the gas–liquid separator before ICPMS detection. As (III), As (V), DMA and MMA can be speciated in real water systems in less than 5 min.

Magnuson et al. described the use of hydrodynamic modified EOF CE (HMEOF) with HG and ICPMS detection for As speciation.[41,71] A microporous PTFE tube was used as a gas–liquid separator. In HMEOF, the EOF in CE was modified by hydrodynamic pressure opposite to the direction of the EOF. HMEOF permits the injection of increased quantities of analytes for sensitivity enhancement. Because of the low flow from the capillary, a makeup buffer flow was used. The capillary ground was also completed through this makeup flow. The CE/HG/ICPMS system was able to speciate arsenic species in real water samples with detection limits down to parts per trillions for As (III) and As (V).

An interesting alternative to the conventional hydrogenation techniques recently reported is the movable reduction bed hydride generation system (MRBHG) developed by Wang and co-workers.[49,78] They have used the MRBHG as an interface in both ICPOES and ICPMS systems. The unique feature of the MRBHG device is its capability to carry out HG reactions in a liquid/solid system at microliter sample volumes, and without the use of gas–liquid separators or the addition of acid solutions to the sample. Instead, the hydride forming reactions take place on the surface of a moving tape which has been precoated with a mixture of dry $NaBH_4$ and solid tartaric acid powders at appropriate ratios. During a CE run, the eluent from the capillary, combined with a makeup flow, is made to drip continuously onto the tape surface. Hydride forming reactions occur upon the contact of the aqueous eluent from CE with the reagents on the surface. The 'reduction-bed' on the tape surface is continuously refreshed by the constant movement of the tape during a run.

Figure 2 Scheme showing the CE/MRBHG/ICPMS system (a) and the MRBHG interface (b).

The construction of the system is shown in Figure 2. In the set-up, the reagent-coated rolling tape is situated inside a sealed reaction chamber. The tape is made to move at a specified rate by turning the two tape rollers that are placed in a sealed organic glass cassette. The tape then crosses the two holes on the stopper into and out of a reaction chamber. The hydrides produced in the chamber are swept into the ICP torch by argon carrier gas.

Compared with conventional HG techniques, MRBHG provides some unique advantages. The major ones include: (1) its ability to handle very small sample sizes down to the μL volumes, (2) it suffers less chemical interference from other co-existing hydride forming elements in the sample matrix, (3) its efficiency in HG is insensitive to solution pH over a wide pH range, (4) its general applicability to all hydride forming elements of different valence state and chemical forms, and finally (5) its low cost of operation since no complicated apparatus is needed. The advantage of the system as a CE/ICP interface is its low dead volume because of the elimination of the use of complex plumbing and the gas–liquid separator.

The above authors have applied the MRBHG interface in both CE/ICPOES and CE/ICPMS systems for the speciation of four arsenic species including As (III), disodium methylarsonate, dimethylarsinic acid and As (V).

The detection limits reported for the optical emission spectroscopy (OES) system were in the range of $0.3\,\mu g\,mL^{-1}$.[78] Much lower detection limits were obtained in the ICPMS system, and the sensitivities observed for the same arsenic species were better than $10\,ng\,mL^{-1}$.[49]

Cyanogen chloride (CNCl) (CAS 506-77-4) is a common disinfection by-product (DBP) formed in chloraminated waters. Cyanogen bromide (CNBr) (CAS 506-68-3), the brominated analog of CNCl, is formed in chloraminated or ozonated waters that are high in bromide. Both CNCl and CNBr are labile in drinking water. They undergo degradation reactions at high pHs or in the presence of free chlorine or sulfite. Because of its potential health effects, CNCl was included in the United States Environmental Protection Agency (USEPA) Information Collection Rule (ICR). Aqueous standards for CNCl are generally prepared with pure CNCl gas. They can also be prepared with chlorinated or chloraminated cyanide (CN^-) solutions. Aqueous standards for CNBr are prepared with commercially available CNBr. For sample preservation, ascorbic acid is commonly used to quench the residual chlorine or chloramines. Acid is often added to lower the pH to prevent possible hydrolysis degradation. There are three methods for analyzing CNCl and CNBr in drinking water samples: purge-and-trap gas chromatography/mass spectrometry (PT GC/MS), headspace gas chromatography/electron-capture detection (GC/ECD), and micro liquid–liquid extraction gas chromatography/electron-capture detection (LLE GC/ECD). All three methods are capable of analyzing microgram per liter levels of CNCl and CNBr in drinking water, and all three give similar method performance, including accuracy, precision, spiking recovery, and method detection limit. The PT GC/MS method is a modification of the USEPA Method 524.2, which requires the use of specialized instrumentation. Because of CNBr's low vapor pressure and high water solubility, the analysis of CNBr also requires a heated purge. Headspace GC/ECD method is a relatively simple and rapid analytical method. As the samples are prepared individually, the method requires a full-time analyst to prepare and inject each sample. However, this analytical procedure can be automated using a commercially available headspace autosampler. In general, micro LLE GC/ECD is a well developed and common procedure for DBP analysis. The micro LLE GC/ECD method, originally developed for CNBr analysis, has been further developed for both CNCl and CNBr analysis in drinking water. The sample injection generally is automated with a common gas chromatography (GC) autosampler.

1 INTRODUCTION

Since chloroform was first reported in chlorinated drinking waters in the 1970s, many DBPs have been identified, including trihalomethanes (THMs), haloacetic acids (HAAs), and other miscellaneous DBPs. To address the concern over the presence of DBPs in finished drinking waters, the USEPA promulgated two DBP regulations, the ICR[1] and the Disinfectants and Disinfection Byproducts (D-DBP) Rule.[2] New maximum contaminant levels (MCLs) have been set by the USEPA for total THMs and five HAAs under the D-DBP rule.[2] Chloramines, which are inexpensive and persistent disinfectants, have been used by many water utilities to control the formation of DBPs. A 1989–90 survey indicated that 20% of the utilities reported using chloramines as part of their THM

Encyclopedia of Analytical Chemistry
R.A. Meyers (Ed.) Copyright © John Wiley & Sons Ltd

minimization program.[3] The percentage could be significantly increased as a result of the D-DBP regulation.

CNCl is a product of the reaction between chloramines and natural organic matter (such as fulvic acid or amino acids). In a survey of 35 water utilities reported by Krasner et al.,[4] CNCl was detected typically in chloraminated water but not in waters containing a free chlorine residual. The concentration of CNCl in chloraminated waters ranged from 1 to 12 $\mu g\,L^{-1}$. CNBr, the brominated analog of CNCl, is formed in chloraminated or ozonated waters that are high in bromide.[5,6] In a water containing 0.11–0.39 $mg\,L^{-1}$ of bromide, 1.5–3.7 $\mu g\,L^{-1}$ of CNBr was reported, whereas concentrations of CNCl were between 9 and 18 $\mu g\,L^{-1}$.[7] In another study, increasing bromide levels increased the concentration of CNBr and decreased the formation of CNCl but had little effect on the sum of the molar concentration of CNCl and CNBr, as shown in Figure 1.[8] At bromide levels of 0.3 $mg\,L^{-1}$ or higher, CNBr became the dominant form.

Both CNCl and CNBr are labile in drinking waters and undergo degradation reactions at high pHs, or in the presence of free chlorine or sulfite. The degradation rates were well studied by two research groups.[9–11] The two studies reported similar CNCl degradation rates at various experimental conditions. At high pHs, both CNCl and CNBr undergo hydrolysis degradation to form cyanate. At pH 10, the half-life of CNCl has been estimated at 43 min,[11] and at 21 min.[9] The half-life of CNBr was reported as 34 min at pH 10.[11] The hydrolysis degradation may significantly affect the stability of CNCl and CNBr in distribution systems or during sample storage. In the presence of free chlorine, CNCl undergoes much faster degradation reactions. At pH 7 and a free chlorine concentration of 0.5 $mg\,L^{-1}$, the half-life of CNCl was 60 min.[11] At pH 9.2 and a free chlorine concentration of 5.68 $mg\,L^{-1}$, the half-life of CNCl was 1.9 min.[9] These results may well explain why high levels of CNCl or CNBr are rarely found in waters containing a free chlorine residual. In the presence of sulfite, CNCl also undergoes degradation reactions. In the presence of 25 μM sulfite and at pH 7, the half-life of CNCl was 76 min, whereas CNBr decomposed completely in 5 min.[11] In another study, the half-life of CNCl was 22 min at pH 7 and in the presence of 78.9 μM sulfite.[10] Therefore, there is a need to be extremely cautious when using sulfite to quench residual chlorine or other oxidants.

Figure 1 Effects of bromide on the formation of CNCl and CNBr. [Reprinted from *Water Research*, Vol. 27, Xie and Reckhow, 'A Rapid and Simple Analytical Method for Cyanogen Chloride and Cyanogen Bromide in Drinking Water', 511, Copyright (1993), with permission from Elsevier Science.]

Because of its hazardous nature and possible health effects, CNCl was listed in the USEPA's first drinking water priority list.[12] CNCl was also included in the USEPA ICR which required water utilities using chloramines to monitor CNCl in their finished water. CNCl may also become regulated under the USEPA Stage 2 D-DBP regulation. Because there are greater health concerns over brominated DBPs, CNBr, a brominated DBP in ozonated and chloraminated waters that are high in bromide, may also be included in future regulations.

2 STANDARDS PREPARATION

Accurate and stable standards are essential for quantitative analyses of environmental contaminants. Standards are needed to prepare calibration curves and determine other method performance parameters. For CNBr standards, the pure chemical can be purchased commercially (e.g. Aldrich Chemical Company, Inc., Milwaukee, WI, USA). For CNCl, pure CNCl gas (Island Pyrochemical Industries, Mineola, NY, USA) or CNCl diluted standards (Protocol Analytical Supplies, Inc., Middlesex, NJ, USA) may be purchased. The instability of CNCl diluted stocks and the hazardous nature and high cost of pure CNCl gas, however, have significantly limited the capability of many laboratories to analyze CNCl samples.[13,14] Under the ICR, as the USEPA could not provide performance evaluation samples or calibration standards, no laboratory was approved for CNCl analysis except the USEPA laboratory. All participating water utilities were requested to send CNCl samples to the USEPA laboratory for analysis.

2.1 Preparation of CNCl and CNBr Standards with Neat Chemicals

CNBr primary methanolic standards are prepared gravimetrically. Using an analytical balance, weigh an exact mass of pure CNBr into 10–50 mL of methanol. CNCl

primary methanolic standards are also prepared gravimetrically. Because of its low boiling point, CNCl is in gas form at room temperature. Prepare CNCl solution as follows.[7,8] Using a glass syringe, equipped with a luer lock adapter and a two-way syringe valve, transfer approximately 15 mL of the pure CNCl to a preweighed 40-mL septum-capped vial containing 10 mL of methanol. Weigh the vial again and use the weight difference to determine the exact amount of CNCl added. This primary standard yields a concentration of approximately 2500 mg L^{-1}. CNCl primary standards can also be prepared by exhausting 10–50 mL of CNCl gas over 10 mL methanol in a volumetric flask.[13]

Secondary or tertiary standard solutions are diluted in methanol from the primary stock. Store both CNBr and CNCl methanolic standard solutions in a −10 °C freezer. These standards are stable for 4–5 weeks.[13] The stability of standards can be improved by using different solvents (e.g. acetone or acetonitrile), as suggested by Protocol Analytical Supplies, Inc. Aqueous standards are prepared by diluting the secondary or tertiary standard with reagent water. Because of the hydrolysis degradation of both CNCl and CNBr, aqueous solutions should be freshly prepared. Aqueous standards should be used to prepare the calibration curves.

CNCl is a highly toxic and volatile chemical. Because of its hazardous nature, CNCl gas is very expensive to purchase, transport and dispose of. The price of a bottle of gaseous CNCl ranges from US $2200 for 0.7 lb to US $700 for 0.5 lb.[14] *Be extremely cautious when using CNCl gas*. Commercial CNCl gas may contain a high percentage of impurities (e.g. hydrogen cyanide) or stabilizers (e.g. tetrasodium pyrophosphate) which may significantly affect the accuracy of the analytical results.

2.2 In Situ Synthesis of CNCl Standards

In situ synthesis of CNCl standards was reported by Wu et al.[14] The method consists of quantitatively converting cyanide to CNCl in the presence of excess free chlorine or chloramine T (sodium *N*-chloro-*p*-toluenesulfonamide). As the CNCl synthesized standards are aqueous standards, there is no need to prepare primary, secondary or tertiary methanolic standard solutions. All chemicals used for CNCl synthesis should be reagent grade or better.

First, using an analytical balance, weigh and dissolve 0.212 g of KCN (CAS 151-50-8) into 100 mL of reagent water.[14] This cyanide stock solution is equivalent to 847 mg L^{-1} of CN^- or 2000 mg L^{-1} of CNCl solution. Take 1 mL of the cyanide stock solution and dilute it into 1000 mL using reagent water. The diluted cyanide solution is the primary cyanide solution. Take 5 mL of primary cyanide solution and dilute it with approximately 30 mL reagent water. Then add 4 mL of phosphate buffer (0.5 M), followed by the addition of NaOCl solution at a chlorine dose between 0.5 and 5 mg L^{-1}. Alternatively, 2 mL of chloramine T solution may be used instead of NaOCl solution. Immediately bring the mixture to 50 mL with reagent water. After exactly 2 min of reaction, add 25 mg of ascorbic acid to quench residual chlorine. After 30–40 s reaction, this primary CNCl standard, with a CNCl concentration of 200 µg L^{-1}, is ready for further dilution to various calibration standard concentrations. Cap the calibration standards headspace-free and store them at 4 °C in the dark.

The free chlorine-generated CNCl was stable for at least 2 days, and 1 h for chloramine T-generated CNCl, as shown in Figure 2.[14] The free chlorine-generated CNCl could be used as a calibration standard or a quality control check sample without repeated synthesis. Because of its instability, chloramine T-generated CNCl needs to be freshly synthesized; however, the synthesis is easily done in less than 10 min.

Figure 2 Stability tests of synthesized standards: (a) generated with hypochlorite; (b) generated with chloramine T. [Reprinted from *Water Research*, Vol. 32, Wu, Chadik and Schmidt, 'An In Situ Synthesis of Cyanogen Chloride as a Safe and Economical Aqueous Standard', 2867, Copyright (1998), with permission from Elsevier Science.]

As reported by Wu et al.,[14] the synthesized CNCl standards are comparable with standards prepared with pure CNCl gas. Microgram quantities of synthesized CNCl are easily disposed of by conversion to innocuous cyanate by simply raising the pH. The in situ synthetic procedure is a safe and economical way to prepare CNCl standards. This procedure is especially useful for laboratories in areas where CNCl is difficult to acquire.

2.3 Commercially Prepared Stock Standards

Commercial CNCl standards at 100, 200, 1000, 2000, or 5000 $\mu g\,L^{-1}$ in acetonitrile are available from Protocol Analytical Supplies, Inc. CNCl standards in methanol or acetone can also be obtained from them upon special request. The standards in methanol are least stable and those in acetonitrile are most stable. Sealed ampules and solvent-diluted standards should be stored at $-10\,^{\circ}C$ until use.

3 SAMPLE COLLECTION, PRESERVATION, AND STORAGE

3.1 Sample Collection

It is recommended that CNCl and CNBr samples are collected in duplicate or triplicate in nominal 40-mL vials with poly(tetrafluoroethylene) (PTFE)-faced septa and threaded polypropylene caps. If the sample is to be taken from a tap, flush the line for approximately 5 min to allow the water temperature to stabilize and to avoid sampling stagnant water. Adjust the flow to a stream that is gentle enough to prevent aeration of the sample and fill the vials. If a preservative is present do not rinse the bottles before filling or allow them to overflow. Seal the sample vials headspace free.

3.2 Sample Preservation

CNCl and CNBr degrade at high pHs or in the presence of free chlorine residual. Formation of CNCl and CNBr may continue if both natural organic matter and a combined chlorine residual are present. Dechlorination and pH adjustment are recommended in combination with cold storage to preserve the samples.

3.2.1 Dechlorination

Any free or combined chlorine residual must be quenched. Approximately 0.1 mL of 25 $mg\,mL^{-1}$ freshly prepared ascorbic acid solution per 40-mL sample is sufficient to remove a chlorine residual of 1 $mg\,L^{-1}$. Add an appropriate amount of ascorbic acid, but avoiding an excess which could degrade CNCl and CNBr. Be extremely cautious when using sulfite to quench free or combined chlorine residual. Both CNCl and CNBr degrade rapidly in the presence of sulfite.[10,11] Trace amounts of sulfite carried over into the purge-and-trap (PT) or GC (e.g. injector or column) system may also significantly impair instrumental sensitivity for CNBr. Ammonium chloride is not a true chlorine quenching reagent. It converts free chlorine to combined chlorine. Addition of ammonium chloride may not stop the continuous formation of CNCl and CNBr in water samples.[15]

3.2.2 pH Adjustment

To prevent the possible hydrolysis degradation of CNCl and CNBr, the pH of the samples must be lowered to 3.0–3.5. For typical drinking waters (i.e. not highly buffered and at pH 7–8), add approximately 0.2 mL of 1 M sulfuric acid to each 40-mL vial. Check the pH of unknown samples on an extra vial.

3.3 Sample Storage

Store samples iced or in a refrigerator at $4\,^{\circ}C$. Typical water samples, even with dechlorination, pH adjustment, and refrigeration, should be analyzed within 48 h for CNBr and within 2 weeks for CNCl.[7] It is best to analyze samples for CNCl and CNBr as soon as possible after collection.

4 ANALYTICAL METHODS

4.1 Purge-and-trap Gas Chromatography/Mass Spectrometry

4.1.1 General Discussion

The PT technique permits introduction of a high analyte concentration into the GC or GC/MS without any accompanying liquid (water or solvent). A high concentration factor is achieved because the analyte from a 25-mL water sample is injected into the GC. Volatile analytes are stripped from the water sample by a stream of nonreactive gas (helium or nitrogen) and trapped on a sorbent (resin or activated carbon). Analytes are desorbed by rapid heating of the trap and are carried into the GC by the carrier gas for separation and detection. With narrow-bore GC columns, a cryo-trap is used to refocus the compounds and reduce peak width. The PT technique has been used for many years for the analysis of volatile organic compounds including solvents and aromatic gasoline components, such as in USEPA methods 524.2[16] and 503.1.[17]

The PT GC/MS method for the analysis of CNCl was first developed by Flesch and Fair[13] using USEPA method 524.2.[16] The PT GC/MS method was the approved method used to collect occurrence data from

U.S. utilities using chloramine residuals under the ICR. Krasner et al. modified the method to include the analysis of CNBr in addition to CNCl.[5] Because CNBr is less volatile than CNCl, the sample had to be heated to achieve effective transfer to the trap. Detection is by mass spectrometry (MS), with spectral identification and quantitation based on a single ion chromatogram.

4.1.2 Sample Preparation and Analysis

Commercial PT systems are available or a system can be built from a fritted gas washing bottle plumbed to a stainless steel trap with deactivated fused silica transfer lines to the GC/MS. First bring samples to room temperature. Pour the sample into a 25-mL gas-tight syringe, insert the plunger, adjust the volume to 25 mL and add fluorobenzene (CAS 462-06-6) internal standard to give a concentration of 0.5 μg L^{-1}. Transfer the sample to the purge vessel and initiate the gas flow. Purge, trap, and desorption and GC/MS operating conditions are given in Table 1.[13,16,17] After purging is complete, switch the gas flow to carry the analytes from the sorbent trap to the GC and heat the trap. Simultaneously, a short piece of deactivated fused silica precolumn is cooled with liquid nitrogen to refocus the analytes. Then ballastically heat the cryotrap to inject the sample onto the analytical GC column. The GC injector is not used. Hold the GC oven at −10 °C from the start of sorbent trap desorption until the start of the GC temperature program at the end of the cryofocusing process.

Aqueous standards of CNCl and CNBr analyzed by the same method should be used to establish a calibration curve based on the ratio of the area of analyte divided by the area of the internal standard. The masses used for quantitation are 61 *m*/*z* for CNCl, 105 *m*/*z* for CNBr, and 96 *m*/*z* for the internal standard, fluorobenzene. Typical spectra for CNCl, CNBr, and fluorobenzene, are shown in Figure 3.

4.1.3 Discussion

Typical gas chromatograms of a PT analysis of CNCl and CNBr calibration standard are shown in Figure 4. The GC run time was less than 9 min. A typical calibration curve for CNCl over a concentration range of 0.2–20 μg L^{-1} was linear with an R^2 value of 0.997, and for CNBr over

Figure 3 Mass spectra of CNCl, CNBr, and fluorobenzene.

a concentration range of 0.5–20 $\mu g\,L^{-1}$ a quadratic fit with an R^2 value of 0.997.[5] The method detection limits, based on seven replicate analyses, were 0.13 $\mu g\,L^{-1}$ for both CNCl and CNBr. However, the CNBr calibration curve does not pass through zero, indicating a threshold concentration. Therefore a minimum reporting limit of 0.5 $\mu g\,L^{-1}$ is used for CNBr. By analyzing 12 treated surface water samples spiked with 5 or 10 $\mu g\,L^{-1}$ cyanogen chloride and cyanogen bromide, the mean recovery was determined to be $96 \pm 18\%$ for CNCl and $88.5 \pm 20.9\%$ for CNBr.[5]

The heated PT GC/MS method was the first method to analyze CNBr in drinking water and provided valuable information about its formation and biodegradation.[5] A good transfer efficiency (25%) was achieved for CNBr. However, the heated PT method is difficult to run continuously because water vapor is carried over to the trapping system. When both CNBr and CNCl analyzes are required, headspace GC/ECD and micro LLE GC/ECD are more cost effective and precise methods. Ambient temperature PT GC/MS is an efficient method for the analysis of CNCl and can be run in conjunction with the determination of other volatile organic compounds. It also provides the advantage of mass-spectral compound identification and can eliminate interference from unresolved GC peaks.

Figure 4 Typical selected ion chromatograms with the PT GC/MS method.

4.2 Headspace Gas Chromatography/Electron-capture Detection

4.2.1 General Discussion

Headspace GC method is a common procedure for analyzing volatile organic compounds in aqueous samples. The analytical procedure includes headspace preparation and GC analysis. The headspace preparation involves transferring volatile substances from the liquid phase into the gas phase (or headspace). Increasing the interfacial area between the gas and liquid phases by shaking the samples increases the efficiency of mass transfer and reduces the time required for reaching the gas–liquid equilibrium. At equilibrium, the concentration of a substance in gas phase is proportional to its concentration in the liquid phase, according to Henry's law. The concentration of the substance in the gas phase is analyzed by GC. The calibration curves are prepared by analyzing aqueous standards at various concentrations. As most of the volatile substances occur in water samples at microgram per liter levels, linear calibration curves are easily obtained.

The CNCl has a boiling point of 13.1 °C at 1 atm. At 20 °C, the Henry's law constant was estimated as 0.9 atm L mol^{-1}.[8] CNBr has a boiling point of 61–62 °C at 1 atm and a Henry's law constant of 0.16 atm L mol^{-1} at 20 °C.[8] These properties indicate that CNCl and CNBr can be easily analyzed by headspace GC/ECD.

4.2.2 Sample Preparation and Analysis

Pour water samples into 40-mL vials without aeration and cap the vials headspace free with PTFE-faced septa and screw caps. Prior to headspace preparation, bring the water samples to ambient temperature (20 °C). An internal standard, 1,2-dibromopropane (CAS 78-75-1), may be added at this point to monitor method performance.[18] The recommended concentration for the internal standard is 50 μg L^{-1}. A bare syringe needle and a syringe equipped with a stainless steel needle are needed to prepare the headspace. First, fill the syringe with 10 mL of nitrogen (99.999%). Force both needles through the septa on the sample vial. The tip of the bare needle should be placed close to the septa and the tip of the syringe needle should be placed in the middle of the sample vial. While keeping the sample vial upside down, gently depress the plunger on the nitrogen-containing syringe. The displaced sample volume is expelled through the bare needle. Remove the needles and vigorously shake the sample vial for 1 min by hand. After settling for 10–20 s, the gas phase is ready for sampling. Withdraw 400 μL of headspace sample using a 1 mL or 500 μL gas-tight syringe, and inject the headspace sample into the GC in the split mode.

A gas chromatograph equipped with a split/splitless injector and an electron capture detector (ECD) is required for CNCl and CNBr analysis. Typical GC operating conditions for headspace GC/ECD are shown in Table 2.[8]

4.2.3 Discussion

Typical gas chromatograms obtained with headspace GC/ECD are shown in Figure 5.[8] Both CNCl and CNBr are well separated. A small negative peak was observed just prior to the elution of CNCl.[8] This caused a non-zero intercept in the calibration curves. This phenomenon was not observed by Sclimenti et al.[18] The calibration curve for CNBr always passed through the origin.[8]

The method detection limits were estimated to be 0.04 μg L^{-1} for CNCl and 0.2 μg L^{-1} for CNBr.[8] By analyzing 11 fulvic acid solution samples (4 mg L^{-1} dissolved organic carbon) spiked with 5 μg L^{-1} CNCl and 10 μg L^{-1} CNBr, the spiking recovery was determined

had little impact on the analytical results.[8] Adding supplemental salt at $100\,g\,L^{-1}$ and/or increasing temperature beyond 25 °C might improve the detection limit for both CNCl and CNBr. However, addition of such large amounts of any salt or heating samples at high temperature would present a new opportunity for contamination or sample degradation, especially for CNBr.

The headspace GC/ECD method is a simple and rapid method for analyzing CNCl and CNBr. The total time for headspace preparation and GC analysis is less than 12 min. Having analyzed more than 250 samples with this method,[8] it was concluded that this method is rapid, simple, and robust.

4.3 Micro Liquid–Liquid Extraction Gas Chromatography/Electron-capture Detection

4.3.1 General Discussion

Liquid–liquid extraction (LLE) is a common concentration procedure for organic analysis. Traditionally a separatory funnel or a continuous extraction apparatus is used to facilitate the extraction of liter-size samples. Micro LLE uses a small volume of water sample and extraction solvent. Generally, the extraction is conducted in a 40-mL sample vial and there is no need to concentrate the extract. Addition of a salt (e.g. sodium sulfate) is used to increase the extraction efficiency and improve the separation of solvent and aqueous phases. This extraction technique has been used for analyzing many DBPs, including THMs (USEPA method 551.1), HAAs (USEPA Method 552.2 and Standard Method 6251), aldehydes (Standard Method 6252), and ketoacids.[19–22]

The micro LLE GC/ECD method was first developed for the analysis of CNBr in ozonated waters.[6] The method used methyl *tert*-butyl ether (MTBE) (CAS 1634-04-4) as the extraction solvent, sodium sulfate as the supplemental salt to increase the extraction efficiency, and GC/ECD for separation and detection. This method was further developed and expanded for analysis of both CNCl and CNBr in chloraminated waters.[7] A similar method was also developed for CNCl analysis,[23] where cyclohexane was used as the extraction solvent.

4.3.2 Sample Preparation and Analysis

Prior to sample extraction, bring the samples to room temperature. Use 40-mL glass vials with PTFE-faced septa and screw caps for the sample extraction. To a vial containing a 30-mL aliquot of sample, add 10 g of Na_2SO_4 and 4 mL of MTBE spiked with $100\,\mu g\,L^{-1}$ internal standard, 1,2-dibromopropane. Shake once or twice to disperse the salt and then proceed to the next

sample. Shake all the vials for 10 min using a mechanical shaker or 2 min by hand. After the solvent and water phases are well separated, transfer the MTBE layer to two 1.5-mL autosampler vials for GC/ECD analysis. The extracts can be stored at 4 °C for 90 days.

A gas chromatograph installed with a septum-equipped, temperature-programmable or split/splitless injector, ECD, and autosampler is needed for CNCl and CNBr analysis. A 30 m × 0.32 mm, 1.8 μm film thickness DB-624 fused silica capillary column or equivalent is needed to obtain baseline resolution of all the analytes. Other operating conditions are listed in Table 3.[7]

4.3.3 Discussion

A typical gas chromatogram of 10 μg L^{-1} of extracted CNCl, CNBr, and calibration standard (1,2-dibromopropane) is shown in Figure 8.[7] All three components are well separated. The GC run time was less than 14 min. A linear calibration curve ranging from 0.5 to 24 μg L^{-1} was obtained for CNCl with an R^2 value of 0.9993, and

Table 3 GC operating conditions for the micro LLE GC/ECD

Parameter	Setting
Analytical column	
Type	DB-624
Length	30 m
Internal diameter	0.32 mm
Film thickness	1.8 μm
Carrier gas	Helium (99.999%)
Carrier gas flow	3.5 mL min^{-1}
Oven temperature program	
Initial temperature	25 °C
Initial holding time	1 min
First temperature ramp	10 °C min^{-1}
Second temperature	120 °C
Second holding time	0 min
Second temperature ramp	35 °C min^{-1}
Final temperature	190 °C
Final holding time	1 min
Injector parameters	
Type	Split
Initial temperature	35 °C
Initial holding time	0 min
Temperature ramp rate	180 °C min^{-1}
Final temperature	200 °C
Final holding time	12.59 min
Split flow	20 mL min^{-1}
Detector	
Type	ECD
Temperature	300 °C
Make-up gas	nitrogen (99.999%)
Make-up gas flow	27 mL min^{-1}

second-order polynomial calibration curves ranged from 0.5 to 24 μg L^{-1} for CNBr with an R^2 value of 0.9993. The method detection limits for CNCl and CNBr were 0.13 and 0.26 μg L^{-1}. By analyzing 10 treated surface water samples spiked with 5–7 μg L^{-1} of CNCl or CNBr the mean recovery for CNCl was 98 ± 6.3%, whereas the mean recovery for CNBr was 100 ± 10%. In another study, the quantitation limit for CNCl was estimated at 0.5 μg L^{-1}.[18]

Four organic solvents were studied by Sclimenti et al.[7] Both hexane and isooctane co-eluted with CNCl and could not be used as the extraction solvents. Pentane extracted both CNCl and CNBr well. In comparison with pentane, however, MTBE gave a better extraction for CNBr, giving a similar extraction efficiency for CNCl. Therefore, the micro LLE GC/ECD method uses MTBE as the extraction solvent.

The effects of a salt, sodium sulfate, and shaking time on the extraction efficiency were also studied.[7] Addition of Na_2SO_4 at a concentration range from 5 g to 12 g per 30-mL aliquot increased the extraction efficiency of CNCl. However, CNBr recoveries began to diminish at the same salt concentration range. This may be due to trace levels of nucleophiles which adversely affect the stability of CNBr.[8] For the LLE GC/ECD method, a salt concentration of 10 g of Na_2SO_4 per 30-mL of aliquot and a shaking time of 10 min were chosen. These parameters represent a compromise among the conditions that were most suitable for each analyte separately.

The micro LLE GC/ECD method is efficient for simultaneously determining both CNCl and CNBr in chloraminated waters. The method performance study showed a high degree of precision and accuracy. Compared to the

PT GC/MS system, the GC/ECD is a much more common system in most water-testing laboratories. The downtime for GC/ECD is significantly less than for GC/MS. Compared to the headspace GC/ECD method, the LLE sample injection could be easily automated with a liquid autosampler.

5 SUMMARY

Both LLE GC/ECD and headspace GC/ECD are viable methods for determining CNCl and CNBr in drinking water. Selection may depend upon the resources of the particular laboratory. The PT GC/MS method (modified USEPA 524.2) can be efficiently used to analyze for CNCl, especially when other volatile solvents are also being determined and when mass spectral identification is desired.

With increasing concern over chemicals that are potential health hazards at low levels, determination of limits of detection and quantification have undergone considerable scrutiny. Most traditional detection limit (DL) estimators suffer from extensive statistical and/or conceptual limitations. In this article, traditional detection and quantification limit estimators are described and critically evaluated. Methods are categorized into decision limits, DLs and quantification limits. The methods are further categorized into single concentration design versus calibration design methodologies. While the single concentration design methods are useful for fixing ideas and clarifying definitions they are shown to be extremely limited in practice since dependence of variability on concentration can be neither estimated nor incorporated. Calibration-based detection and quantification limit estimators are described, compared and contrasted. Discussion of nonconstant variance, multiple future detection decisions and simultaneous control of Type I and II errors is provided. The various methods are illustrated using real data and experimental design issues for DL studies discussed.

1 INTRODUCTION

Of critical concern in protection of human health and the environment is the earliest possible detection of hazardous environmental constituents (i.e. air, surface water, groundwater, drinking water). The very presence of anthropogenic compounds in environmental media may lead to assessment and potential remediation of industrial activity. As an example, the presence of vinyl chloride, a known carcinogenic initiator, in a groundwater sample obtained from a monitoring well located downgradient of a hazardous or municipal waste-disposal facility may result in an expensive site assessment, possible corrective action or closure of the faculty. In some cases, these consequences may be the result of a single detection decision in a single environmental sample. In other cases, the measured concentration of a constituent is compared with a concentration limit, possibly health-based, and if the measured concentration exceeds the limit, remedial action is taken. Unfortunately, in many cases the limit of detection for the constituent in a particular medium (e.g. surface water) is reported to be considerably larger than the health-based concentration limit. There is public concern regarding protection of human health and the environment in that potentially harmful levels of a chemical may exist in the environment but since they are undetectable no regulatory impact decision can be made.

In response to these concerns there has been tremendous motivation to develop new analytical methods capable of detecting these compounds at lower levels. Furthermore, these concerns have led to a proliferation of new definitions and statistical approaches to estimating limits of detection. These new definitions and statistical estimators often lead to further confusion and suffer from statistical and conceptual errors.[1–3] New methods proposed for setting limits on detection may result in lower limits regardless of the actual analytical capabilities of the method.

Unfortunately, virtually all practical applications of environmental detection decisions in the United States are based on the most severely limited of the definitions.[4,5] They are carried out by the United States Environmental Protection Agency (USEPA). Not only are the statistical problems with USEPA's estimator, termed the method detection limit (MDL), insurmountable but the use of this estimator has led to the routine practice of setting DL at lower and lower levels regardless of the true analytical capabilities of the method and/or laboratory. The purpose of this article is to illustrate these statistical limitations and to provide a review of less problem-prone alternative estimators. To do so, this article reviews a variety of methods from both statistical and conceptual frameworks. The intended audience is both the statistician interested in environmental applications and the environmental scientist interested in the conceptual and statistical foundations of limits of detection. Public policy in these areas has not been adequately examined in either the statistical or chemometric literatures.

There are a myriad of terms for limits of detection: MDL, DL, instrument detection limit (IDL), practical method detection limit (PMDL) etc. However, their conceptual foundations as well as implementation algorithms are often quite diverse, leading to tremendous inconsistency in practice. To provide a framework to compare and contrast these various methodologies the pioneering definitions of Currie[6] are used, since they form the basis of most approaches. Currie defined two levels; the ''decision limit'' and the ''DL''. The decision limit is the measured concentration ''at which one may decide whether or not the result of an analysis indicates detection''.[6] The DL is the true concentration ''at which a given analytical procedure may be relied upon to lead to a detection''.[6] From a statistical perspective, the decision limit is the critical value for a test of the null hypothesis ''analyte absent'' versus the alternative hypothesis ''analyte present''. Note that the DL is a direct function of the selection of the critical value.

Operationally, the decision limit or critical level L_C, is the measurement above which the response signal significantly differs from zero. When a measurement exceeds L_C we can make the binary decision, ''detected''. Note that when the true concentration is zero, the probability of the correct decision, ''not detected'' is $1-\alpha$ where α is the Type I error rate or false positive rate of the statistical test (e.g. $\alpha = 0.01$). Assuming a symmetric distribution of measurement errors, when the true concentration is equal to L_C the probability of reporting it below L_C is 50%. This is termed the Type II error rate or false negative rate (β). To control both Type I and II errors Currie then developed the DL L_D. When the true concentration is L_D, then the Type II error rate (β) using L_C as the decision limit is small. For example, if we assume that $\alpha = \beta = 0.01$, then another way of stating this is that 99% of the measurements for samples not containing the analyte will be less than the decision limit L_C and 99% of the measurements with true concentration at the DL L_D will exceed the decision limit L_C.[7]

Investigators have defined the limit of detection to include control of both false positive and false negative rates, varying levels of confidence, uncertainty in the concentration mean and variance and in the calibration function that relates instrument response to concentration, variance components related to multiple instruments and analysts, application to multiple future detection decisions, and nonconstant variance and baseline instrument response.[1,6,8–12] However, these operational definitions may cloud the distinction between decision limits and DLs (as an example see Glaser et al.[5])

An alternative approach and review of many of these issues can be found in Lambert et al.[7] and Hastie and Tibshirani[13] The method introduced by Lambert et al. provides much information regarding the statistical properties of low-level analytical measurements conditional on a fixed and pre-existing method of making binary detection decisions, but does not provide an independent estimate of the limit of detection. In a sense, Lambert's method models the detection criterion of the analyst but not the actual capabilities of the analytical method itself.

In the following sections we examine the strengths and weaknesses of a variety of approaches to the problem of estimating limits of detection in use or proposed for widespread application. These approaches fall into two general categories; single concentration-based methods and calibration-based methods. Methods based on single concentration designs are useful for fixing ideas and definitions, particularly the critical distinction between decision limits and DLs. In general single point designs lead to problems which severely limit their use in practice which can be eliminated through use of calibration-based methods. These methods are fully described and classified as decision limits or DLs. Generalization of calibration-based methods to problems of nonconstant variance, multiple future detection decisions and alternative approaches to controlling Type I and II error rates are presented. Application of the various methodologies are illustrated using real data and experimental design considerations are discussed. Following discussion of DLs, various estimators of the quantification limit are described and illustrated.

2 DETECTION LIMITS FOR SINGLE CONCENTRATION DESIGNS

Single concentration designs involve spiking a series of n samples with a fixed concentration of a compound

and using variability in instrument response at that concentration to derive a decision limit, DL or both. In the following, the major strategies for estimating decision limits and DLs from single concentration designs are described.

2.1 Kaiser–Currie Method

Based on developments due to Kaiser[14–16], Currie[6] described a two-stage procedure for calculating the DL L_D. At the first level of analysis, Currie computes the decision limit L_C (Equation 1) as:

$$L_C = z_{1-\alpha}\sigma_0 \tag{1}$$

where σ_0 is the population standard deviation of the response signal when the true concentration (x) is zero (i.e. the standard deviation of the net signal found in the population of blank samples),
and $z_{1-\alpha}$ is a multiplication factor based on the $(1-\alpha)100$ percentage point of the standardized normal distribution.

For example, the one-sided 99% point of the normal distribution is 2.33; therefore, the decision limit (Equation 2) for a 1% false positive rate is defined as:

$$L_C = z_{1-\alpha}\sigma_0 = 2.33\sigma_0 \tag{2}$$

As discussed, when the true concentration is equal to L_C and the measurement error distribution is symmetric, the Type II error rate at the decision limit is 50%. That is, we have a 50% chance of declaring that the analyte is not present when the analyte in fact is present at the decision limit. To provide an acceptable Type II error rate, Currie defined the DL (L_D) (Equation 3) as

$$L_D = L_C + z_{1-\beta}\sigma_D \tag{3}$$

where σ_D is the population standard deviation of the response signal at L_D (or net response signal after subtracting the background signal),
and β is the acceptable Type II error rate (i.e. false negative rate).

Currie points out that if we make the simplifying assumption that $\sigma_0 = \sigma_D$ (i.e. the variability of the signal is constant in the range of L_C to L_D) and that the risk of false positive and false negative rates is equivalent (i.e. $z_{1-\alpha} = z_{1-\beta} = z$) then the DL is simply (Equation 4):

$$L_D = L_C + z_\beta\sigma_D = z(\sigma_0 + \sigma_D) = 2L_C \tag{4}$$

or twice the decision limit. For $\alpha = \beta = 0.01$, the DL is therefore $4.66\sigma_0$. If the true concentration is L_D then the probability of a measured valued below L_C is 1%.

In reviewing Currie's method it is critically important to note that the only case considered is the one in which the population values σ_0 and σ_D are known. In practice, however population values are never known and the methods described in following sections are required to incorporate uncertainty in sample-based estimates of these statistics in decision-limit and DL estimates.

2.2 United States Environmental Protection Agency 40CFR 136

Glaser et al[5] defined the MDL as "the minimum concentration of a substance that can be identified, measured and reported with 99% confidence that the analyte concentration is greater than zero", and that "on average, 99% of the trials measuring the analyte concentration of the MDL must be significantly different from zero". The first definition is in terms of true concentration and could therefore be interpreted as L_D. Similarly, if one interprets "significantly different from zero" as greater than L_C, which is reasonable, then the MDL as conceptually defined is also consistent with L_D. Unfortunately, their derivation converges asymptotically to an estimate of the 99th percentile of the distribution of measurements at concentration $x = 0$, which is, of course, L_C. These definitions have been adopted by USEPA[4] and the MDL is used in establishing all published DLs under USEPA regulations for environmental monitoring of drinking water, groundwater and surface water. In addition, all laboratories performing analyses under these regulations must be certified on the basis of meeting published MDLs using this method.

In constructing a model for the MDL, Glaser et al.[5] initially assume that variability is a linear function of concentration, (Equation 5) such that:

$$s_x = b_0 + b_1 x \tag{5}$$

where s_x is the standard deviation of n replicate analyses at concentration x and b_0 and b_1 are the intercept and the slope of the linear regression of standard deviation on concentration. They define the MDL (Equation 6) to be that concentration x for which:

$$t_x = \frac{x}{s_x/\sqrt{n}} \tag{6}$$

holds when t is set equal to the 99th percentile of Student's t-distribution with $n-1$ degrees of freedom. At this point Glaser et al. make two simplifying assumptions. First, they set b_1 to zero, therefore (Equation 7):

$$\text{MDL} = \frac{t_{[0.01,n-1]}b_0}{\sqrt{n}} \tag{7}$$

Second, they assume that $s_x = b_0/\sqrt{n}$, therefore (Equation 8):

$$\text{MDL} = t_{[0.01,n-1]}s_x \tag{8}$$

where s_x is defined as the standard deviation of n analytical replicates spiked at a single concentration x.

There are numerous problems with this model. First, having started with a conceptual definition that sounds promisingly like L_D they derive a mathematical definition that corresponds to L_C. This highlights the major distinction between the MDL and the other methods reviewed here. Second, having started with the useful generalization, variance allowed to be a function of concentration, they remove it by assuming $b_1 = 0$ and using a single concentration to estimate s_x. To estimate b_0 and b_1 would require multiple samples at each of several concentrations (i.e. a calibration design). Third, there are inexplicable inconsistencies about whether $s_x = b_0$ (per Equation 6 after you set $b_1 = 0$) or $b_0/\sqrt{n}$ as asserted in the sidebar in Glaser et al.[5] Of course, $b_0/\sqrt{n}$ is the standard error of measurement at $x = 0$, not the standard deviation at concentration x.

It seems odd that the initial assumption of this model is that variability is dependent on concentration, yet in practice the observed standard deviation for seven replicates is used regardless of the concentration at which the sample is spiked. In practice, laboratories demonstrate they can achieve low state and federally mandated MDLs (used as decision limits, not DLs) by spiking at progressively lower concentrations. Glaser et al. suggest that the spiking concentration should be close to the "true MDL"; however, since the true MDL is unknown, the spiking concentration is often set at risk-based standards (e.g. a maximum contaminant level – MCL) and can be well below the true MDL. Since Glaser et al. assume that the s_x is a linear function of concentration, this practice can lead to a gross underestimate of the true MDL.

It should be noted that despite the obvious limitations of the statistical derivation of the MDL, the underlying conceptual framework foreshadows some of the ideas of calibration designs. Conceptually, the underlying model assumes that the measured value is normally distributed with mean equal to the true concentration x and standard deviation $b_0 + b_1x$. This conceptual model leads directly to many of the statistical results for calibration designs but is intractable for single concentration designs since b_0 and b_1 are unknown and cannot be estimated from a single concentration. Unfortunately, USEPA continues to use the MDL as the basis for regulatory detection decisions. The MDL also forms the basis for the new approach USEPA has taken to quantification, the minimum level (ML) which is computed as 3.18 MDL.[17]

2.3 Prediction Limits

Prediction limits were apparently not considered in the context of single concentration designs. Nonetheless they are more relevant to making detection decisions than either the MDL or the Kaiser–Currie method. A prediction limit provides a certain level of confidence (e.g. 99%) of including the next single measurement based on a previous sample of n measurements. If we consider a single future detection decision, then the decision limit (Equation 9) based on a prediction limit[18] for a normally distributed instrument response is

$$L_C = t_{(n-1,\alpha)}s_0\sqrt{1 + \frac{1}{n}} \tag{9}$$

where s_0 is an estimate of σ_0 (i.e. the standard deviation in blank samples). For the seven replicate samples required by USEPA, the decision limit (Equation 10) becomes

$$L_C = 3.14s_0\sqrt{1 + \frac{1}{7}} = 3.36s \tag{10}$$

where $\alpha = 0.01$. Assuming $s_0 = s_D = s$ and $\alpha = \beta$ the DL (Equation 11) can be approximated by

$$L_D = 2t_{(n-1,\alpha)}s\sqrt{1 + \frac{1}{n}} = 2L_C \tag{11}$$

however, this is an invalid use of the central t distribution since the statistic $\sqrt{n}x/s$ has a noncentral t distribution when $x > 0$ (i.e. in computing L_D, $x = L_C$).

2.4 Tolerance Limits

In practice, a limit of detection is computed and applied to a large and potentially unknown number of future detection determinations. As such, the prediction limit described in the previous section may not be relevant to many situations because the error rate pertains to a single future detection decision. An alternative is to base the decision limit on a statistical tolerance limit that will contain a proportion of all future measurements (e.g. 99%) with a specified level of confidence (e.g. 99%). Tolerance limits are well known in the statistical literature and have been described in detail by Guttman[19] with corresponding tables relevant to this application. In this context (Equation 12), the decision limit becomes

$$L_C = K_{(P,\alpha)}s_0 \tag{12}$$

where values of K for varying coverage proportions (P) and confidence levels $(1 - \alpha)$ are available in tabular form.[11,18,19]

Following USEPA guidance using seven replicate samples, the decision limit would be $6.41s_0$, and would provide 99% confidence of including 99% of all future

measurements when the true concentration is zero. Of course, as the number of background samples n increases, the size of the multiplier decreases. Use of tolerance limits to compute the DL is not straightforward; however, an approximate method has been developed.[10]

2.5 Simultaneous Control of False Positive and False Negative Rates

The distinction between decision limits and DLs is based on simultaneous control of both false positive and false negative rates. When the population parameters σ_0 and σ_D are known, as was assumed by Currie, repeated application of the normal multiplier $z_{1-\alpha}$ followed by $z_{1-\beta}$ is appropriate. In practice however, σ_0 and σ_D are unknown and are replaced by their sample-based estimates s_0 and s_D provided by a sample of n spiked measurements. In this case repeated application of Student's t distribution (i.e. $t_{1-\alpha}$ and $t_{1-\beta}$) is incorrect. In computing L_C, the true concentration $x = 0$ and the false positive rate of the decision limit is based on Student's t distribution. In computing L_D the true concentration $x = L_C$ and the statistic $\sqrt{n}x/s_0$ has a noncentral t distribution on $n - 1$ degrees of freedom.[1,10] Relevant tabled values of the noncentrality parameters $\phi(n-1, \alpha, \beta)$ are also available.[1,10] For the case of $n = 7$ measurements and false positive and false negative rates of 1%, the limit of detection is $\phi(6, 0.01, 0.01)s_0 = 6.64s_0$. Although this limit of detection considers both false positive and false negative rates it pertains only to a single future detection decision. Gibbons et al.[10] have further generalized the result to include coverage of a specified proportion of all future values and have provided a corresponding table of multipliers (also see Gibbons[11]).

2.6 Limitations

The critical assumption underlying single concentration designs is that variability is homogeneous in the range of possible spiking concentrations and the true limit of detection. This assumption is implicit in the use of observed spiking concentration variance as an estimator of the true variance at the limit of detection. This assumption is rarely realized in practice. As a typical example, consider the calibration function presented in Figure 1.

For the purpose of illustration, actual concentrations are presented on the x-axis and measured concentrations are presented on the y-axis. In practice, the y-axis should represent actual peak area ion counts prior to calibration. Ignoring this step will lead to ignoring uncertainty in the calibration function, never known with certainty.

Figure 1 displays calibration data for silver using USEPA Method 1638[20] in distilled water. These data were obtained under controlled nonblind conditions that are not representative of routine practice. Spiking concentrations were 0, 10, 20, 50, 100, 200, 500, 1000 ppt. The center line that passes through these data represents the weighted least squares (WLS) estimate of the linear calibration regression line. The curvilinear functions that provide an interval surrounding the data are WLS prediction bands and provide 99% confidence of including the next single measurement at a given concentration.

Inspection of Figure 1 reveals that variability increases with increasing concentration. In fact, this same pattern

Figure 1 Linear calibration assuming increasing variance based on Rocke and Lorenzato Model: Method 1638 Silver (ppt) – prediction interval.

was observed for each of 8 other compounds. The prediction bands, which are based on the assumption that variability increases with concentration, fit the observed measurements extremely well. Of the 56 measurements (i.e. 7 replicates of each of the 8 spiking concentrations) one measurement is beyond the prediction bands, and therefore consistent with the 99% confidence level. The implication of this finding is that the driving force behind limits of detection from single concentration designs is the concentration at which the samples are spiked. To illustrate this point, Table 1 displays the USEPA/Glaser et al. MDL estimator applied to the data in Figure 1 at various concentrations.

Table 1 reveals that USEPA's MDL estimator will yield values ranging from 67.29 ppt to 1.47 ppt from exactly the same data. If a new analytical method with lower limits of detection were developed, presumably it would be tested by spiking at a correspondingly lower concentration. Thus, regardless of the true analytical properties of the method a lower MDL will be found.

Anticipating this problem to some extent, Glaser et al. suggest both a single-step and an iterative approach to computing the MDL (also described in USEPA's adoption of the procedure). For the single-step approach they recommend spiking samples at a concentration between one and five times the best estimate of the true MDL. They note that it is possible that an incorrect MDL could be obtained even if the spiking concentration were less than five times the computed MDL, illustrated in the higher values in Table 1. This logic requires that we know the actual MDL, which never happens in practice. In this case they recommend an iterative approach in which successively lower concentrations are computed until the pooled variance stabilizes. They note that convergence of the iterative procedure depends on the closeness of the estimated MDL to the calculated MDL. They also note that if the calculated MDL is lower than the background level of the analyte, the iterative procedure cannot be used.

Table 1 USEPA 40CFR MDL at various spiking concentrations of silver in distilled water using method 1638 in ppt

Concentration	SD	MDL
0	0.47	1.47
10	0.67	2.09[a]
20	0.66	2.06
50	1.08	3.40
100	2.23	7.00
200	15.32	48.10[a]
500	9.05	28.43
1000	21.43	67.29

[a] Meets USEPA's 5 : 1 criterion.

Inspection of Table 1 reveals that spiking concentrations of 200 ppt and 10 ppt both meet USEPA's criterion of a spike to MDL ratio of 5 : 1 or less. Presumably, if we had started at higher concentrations and iteratively decreased the spiking concentration we would obtain an MDL of 48 ppt. Alternatively if we started at zero and worked up, we would have obtained an MDL of 2 ppt. This level of arbitrariness is unacceptable in a DL estimator and can lead to both false positive and false negative regulatory impact decisions based on samples spiked at higher or lower concentrations. For this reason, single concentration decision limits and DLs are of little practical value despite their widespread use.

3 DETECTION LIMITS FOR CALIBRATION DESIGNS

An alternative method for estimating DLs is a calibration design. In this case, a series of samples are spiked at known concentrations in the range of the hypothesized DL, and variability is determined by examining the deviations of the actual response signals from the fitted regression line of response signal on known concentration. In these designs, it is generally assumed that the deviations from the fitted regression line are normally distributed.

There are two major advantages of calibration designs over single concentration designs. First, single concentration designs ignore uncertainty in the calibration function that relates measured to true concentration. Second, when variability in measured concentration is a function of true concentration, the estimated DL, based on a single concentration design, will depend in large part on the spiking concentration selected by the analyst. If different laboratories select different spiking concentrations, it will appear that they have different analytical capabilities when they may, in fact, be identical. This is not a problem for calibration-based DLs since the relationship between variability and concentration can be explicitly modeled and incorporated into the DL estimator.

Proponents of single concentration designs suggest that nonconstant variance can only lead to overestimates of the true DL since variability at a concentration greater than zero will be larger than the variability when the analyte is absent. In many cases this is true, and artificially high DLs can result. However, if a very low spiking concentration is selected, gross underestimation of the DL is also possible. Modern analytical instruments are often designed to censor measured concentrations less than zero. If the spiking concentration is close to zero, then we would expect up to 50% of the measured concentrations to be negative. However, if the instrument assigns a concentration of zero to these samples, the estimated

Figure 2 Linear calibration assuming constant variance: Method 1638 Silver (ppt). Prediction interval with Hubaux–Vos type estimates of L_C and L_D graphically depicted.

standard deviation will be a gross underestimate of the true population standard deviation. To make matters worse, many instruments use peak area rejection criteria so that even positive concentrations of low magnitude will also be assigned a measured concentration of zero. Again, this practice will lead to even further underestimates of variability and corresponding DLs. Calibration designs are immune to such problems since concentrations both above and below the true DL are included and nonconstant variance accommodated. The primary disadvantage of calibration based DL estimators is that they are more complicated to compute and typically will require a computer program capable of unweighted least squares (ULS) regression and/or WLS regression. Fortunately computer programs for these computations are now becoming readily available.[21,22]

Hubaux and Vos[8] were the first to describe a procedure for calibration based DL estimation. Beginning from a calibration design in which response signals are determined for analyte-containing samples with concentrations throughout the range of L_C to L_D, they constructed a 99% prediction interval for the calibration regression line (see Figure 2). The prediction interval is given by Equation (13):

$$\hat{y}_x \pm t_{[1-\alpha/2,n-2]} s(\hat{y}_x) \tag{13}$$

where $s(\hat{y}_x)$ is the estimated uncertainty of a predicted instrument response (or measured concentration) $\hat{y} = b_0 + b_1 x$ at true concentration x (see Appendix). The DL is defined as the point at which we can have 99% confidence that the response signal is greater than L_C; therefore, Hubaux and Vos suggest that the response signal be obtained graphically by locating the abscissa corresponding to L_C on the lower prediction limit (see Figure 2). A more direct solution for L_D is provided in the technical Appendix.

The method of Hubaux and Vos assumes that variability is constant throughout the range of concentrations used in the calibration design. If this assumption is violated, then the DL will be overestimated because variability at high concentrations are given equal weight as those at lower concentrations. Clayton[1] suggested a variance-stabilizing square-root transformation which helps to some extent but does not eliminate the problem. Oppenheimer[23] proposed an estimator of L_D based on WLS regression which provides a general solution to this problem but requires an iterative solution (see Appendix 1). Gibbons et al.[10] provide a noniterative computing approximate and further generalize this result to the case of multiple future detection decisions by substituting tolerance limits for prediction limits. See Gibbons[3,11] for a review of this literature.

3.1 Illustration

Figures 1–5 display actual and measured concentrations of silver in seven eight-point concentration calibrations. Figure 2 represents the same data as in Figure 1, but assumes constant variance and provides corresponding Hubaux–Vos estimates of L_C and L_D. Figure 2 reveals that if we assume constant variance, in order to incorporate larger variability at higher concentrations, variability is overestimated at the lower concentrations. In contrast, the WLS approach described in Figure 1 provides excellent fit to the observed data for both high and low true concentrations. Figure 3 represents the same data as Figure 1 but shows error bands based on a statistical tolerance interval with 95% confidence and 99% coverage. Figure 3 reveals that substitution of tolerance

Figure 3 Linear calibration assuming increasing variance based on Rocke and Lorenzato Model: Method 1638 Silver (ppt) – tolerance interval.

Figure 4 Linear calibration assuming proportional variance: Method 1638 Silver (ppt) – prediction interval. $L_D = 0.545$.

intervals for prediction intervals provides slightly wider intervals but yields DLs that will include 99% of all future detection decisions whereas prediction limits only provide this level of confidence for a single future detection decision. Figure 4 displays the WLS approximate prediction limits described by Gibbons et al. based on the assumption of proportional variance and concentration. Figure 4 reveals quite similar results to Figure 1 where variance is explicitly modeled. Figure 5 displays the WLS approximate tolerance intervals based on the assumption of proportional variance and concentration. Again, the approximation appears to provide similar results to the case in which variance is explicitly modeled as in Figure 3.

Table 2 presents estimated DLs for several of the previously described approaches.

Inspection of Table 2 reveals that, as expected, the Hubaux–Vos ULS approach assuming constant variance yields a much higher DL than the WLS approaches which assume that variability is an increasing function of true concentration. Once nonconstant variability is accounted for, we pay a very modest price for generalizing the limits to apply to 99% of all future detection decisions as opposed to the next single detection decision (e.g. 5.6 ppt versus 3.6 ppt). The approximate noniterative solution suggested by Gibbons et al. works well in this example. Note that the calibration-based estimates of L_C and L_D

Figure 5 Linear calibration assuming proportional variance: Method 1638 Silver (ppt) – tolerance interval.

Table 2 Comparison of calibration-based DL estimators for constant (ULS) and nonconstant (WLS) variance silver via method 1638 in ppt

Model	L_C	L_D	Figure
Hubaux–Vos (ULS)	19.955	39.895	2
WLS PL[a] – $WT = x$	1.878	2.695	4
WLS PL[b] – $WT = 1/s_x^2$	1.790	3.591	1
WLS TL[a] – $WT = x$	2.773	4.233	5
WLS TL[b] – $WT = 1/s_x^2$	2.792	5.613	3

[a] Gibbons[22] noniterative solution.
[b] Oppenheimer[23] iterative solution.

appear to be quite reasonable given the data displayed in Table 1. Note that these data were obtained under highly controlled ''clean lab'' research conditions in distilled water and the DLs obtained here may be considerably higher in routine practice. Nevertheless, these results clearly reveal that calibration-based methods do not necessarily lead to higher DL estimates than their single concentration counterparts (e.g. the MDL).

4 EXPERIMENTAL DESIGN OF DETECTION LIMIT STUDIES

A detailed review of the principles of experimental design of DL studies would easily require a chapter to itself and has been reviewed in some detail by others.[2,24] There are several guiding concepts critical for producing unbiased DL estimates of practical relevance.

First, in analyte present studies, the analysts must be blind to both the number of compounds in the sample and to their spiking concentrations. To achieve this goal, the number of compounds must vary (perhaps randomly) from sample to sample. Furthermore, the concentration of each constituent should vary both within and across samples. Without ensuring that the analyst is blind to both presence and concentration of the analyte under study, the resulting DL simply cannot be applied to routine practice in which such uncertainty must always exist. In practice, it is often impossible to execute such studies since numerous samples would have to be prepared at widely varying concentrations. In the absence of this level of experimental control, standard calibration data in which the analysts are unaware that they are being tested may have to suffice. The critical issue is that the analysts must *not* go back and retest samples that appear to be anomalous relative to the known spiking concentration.

Second, two or more instruments and analysts must be used and the assignment of samples to analysts and instruments must also be random. Since in large production laboratories, any one of a number of analysts and/or instruments may be called upon to analyze a test sample, this same component of variability must be included in determining the DL.

Third, if multiple laboratories are used or a regulatory agency analyzes split-samples or additional samples from the facility, then the entire DL study must be replicated in multiple laboratories. Data from a single laboratory should only be used when it is technically unfeasible to provide common calibration standards, or to split common standard samples, or a dedicated laboratory is used for all relevant analyses.

Fourth, the number of samples selected should be based on statistical power criteria, such that a reasonable

balance of false positive and false negative rates is achieved. For example, if we estimate σ by computing s on seven samples, our uncertainty in σ will be extremely large and our resulting DL estimate L_D will also be quite large. By increasing the number of samples to say, 25, we achieve a much more reasonable estimate of σ, and resulting L_D are greatly reduced. The cost of running a few additional samples is far cheaper than dealing with the drawbacks of using DLs incapable of detecting anything but the largest signals.

An additional note regarding analyte-absent experiments (i.e. blank samples): rather than running a series of blank samples at once, they should be randomly entered into the analysts' work load throughout the course of the day. The purpose of this approach is to ensure that the analysts are blind to sample composition. The broader question is whether analyte-absent experiments are relevant to establishing DLs. It can be argued that the properties of the *method* can only be evaluated when the analyte is present, at least in some of the samples. The general recommendation of calibration designs over fixed-concentration designs allows for a mixture of samples in which the analyte is present and absent.

There are several experimental designs that can fulfill the preceding requirements. When the number of samples is large, say $n = 30$, one possibility is to give each compound in the study a 0.5 probability of being in any given sample, and once selected, its concentration could also be randomly selected from a uniform distribution covering the range of 0 to $2L'_D$, where L'_D is the presumed DL. This design may be optimal to ensure blindness, but it may not be necessary to maximize the signal-to-noise ratio which increases the amount of information gained in such a study. For example, Hubaux and Vos[8] suggest a three values repartition, in which n_1 replicate samples with concentrations at the lowest permissible content (x_1), $n_2 = n - n_1 - 1$ samples at the highest "permissible content" (x_2) and a single sample at $(x_1 + x_2)/2$ are selected. They find that this design minimizes the number of required standards for a fixed level of sensitivity.

Liteanu and Rica,[24] review a wide variety of sampling designs for DL studies, including response surface designs, fractional factorial designs and rotatable designs. Youden pair-type designs are excellent candidates for maintaining blind and unbiased DL studies.

Finally, in any design in which there are multiple components of variability (e.g. analyst, instrument, laboratory), appropriate steps must be taken to obtain unbiased estimates of variability. The naive estimator of σ which is obtained by computing s in the usual way with all measurements should be replaced by the unbiased variance estimate based on the appropriate variance components model for the problem at hand.[25,26]

5 QUANTIFICATION LIMITS

Quantitative determination in analytical chemistry is a two-stage process. First, we must make the binary decision of whether or not the compound is present in the sample. Second, in the event the compound is present, we must determine if the estimated concentration supports quantitative determination. The first determination is governed by the DL as discussed in the previous sections. In contrast, very little literature exists on the second stage of the decision process, i.e. quantification. Currie[6] originally described the "determination limit" (L_Q) as the concentration at which the relative standard deviation (RSD) is 10% (i.e. a signal-to-noise ratio of 10 to 1). Gibbons et al.[27] have provided a more statistically rigorous estimator of L_Q that accommodates effects of nonconstant variance, uncertainty in the parameters of the recovery curve and uncertainty in the sample-based estimator of the true population variance. More recently, USEPA[17] has defined the ML as the method DL (defined in 40CFR Part 136 App. B[4]) multiplied by a factor of 3.18. USEPA is using the ML as a quantification limit above which measured concentrations can be directly compared to regulatory standards and compliance decisions can be made. In an attempt to provide an estimator that is conceptually similar to the ML, but with fewer statistical limitations, Gibbons et al.[28] have developed an "Alternative Minimum Level" (AML). In the following, strengths and weaknesses of these various alternatives are explored.

5.1 The United States Environmental Protection Agency Minimum Level

USEPA[17] has defined the ML (Equation 14) as:

$$\mathrm{ML} = 3.18\ (\mathrm{MDL}) = 3.18(3.14)s_x = 10s_x \qquad (14)$$

where s_x is the standard deviation of 7 replicate measurements spiked at true concentration x. All limitations previously described for the USEPA MDL apply equally to the ML since it forms the basis for this estimator, i.e. the MDL and hence the ML is a direct function of the choice of spiking concentration x. In addition, it is of critical importance to understand that the ML is not based on the permittee's MDL, but rather on a single MDL developed by a single USEPA laboratory under ideal conditions. This further reduces generalizability of the ML to application under routine conditions in which analysts are blind to the true concentration and any one sample can be analyzed by different analysts, instruments and even laboratories.

5.2 Alternative Minimum Level

The fundamental problem with the ML is not its definition (i.e. $10s_x$) but the fact that the sample standard deviation s_x is a moving target and depends completely on the choice of spiking concentration x. As previously noted, the ML suffers from numerous other problems in that it completely ignores interinstrument, interanalyst and interlaboratory components of variation, but this has more to do with the way in which USEPA has applied the method and not the statistical derivation itself. It is the statistical derivation that we focus on in developing the AML.

As a conceptual foundation, Currie defined the determination limit L_Q (Equation 15) as

$$L_Q = 10\sigma_Q \tag{15}$$

where σ_Q represents the true population standard deviation at the determination limit L_Q. The L_Q is based on the idea that quantitative determinations can be confidently made when the signal-to-noise ratio is ten to one (i.e. a RSD of 10%).[6] Unfortunately, in the real world, we never know the population standard deviation (i.e. it must be estimated from a sample of n measurements) and in many cases, the proportionality constant between the standard deviation and concentration is larger than 10% in the practical calibration range and therefore a 10% RSD may not be achievable or only achievable at unacceptably high levels.

A reasonable alternative to both approaches is to compute the standard deviation at the lowest concentration that is differentiable from zero and use that standard deviation in computing the ML. In this way, the spiking concentration is no longer arbitrary and the effect of nonconstant variance is incorporated up to the lowest nonzero concentration. Of course, this alternative ML (AML) will not guarantee a 10%RSD at the AML; however, we can compute the actual %RSD at the ML by modeling the association between s and x. The algorithm is as follows:

1. Using calibration data, model the relationship between s and x, for example an exponential function (Equation 16)

$$s_x = a_0 e^{a_1(x)} \tag{16}$$

   The exponential model $s_x = a_0 e^{a_1 x}$ generally provides excellent fit to the observed data and it will be used in the following discussion. However, the model suggested by Rocke and Lorenzato[29] (see Appendix) is also an excellent choice. The Rocke and Lorenzato model was used in generating the prediction intervals in Figure 1. The exponential model can be fitted using nonlinear least squares (e.g. Gauss–Newton) or by ULS regression of natural log transformed measured concentration on actual concentration (Snedecor and Cochran, p. 397[30]).

2. Compute the WLS regression of measured concentration or instrument response (y) on true concentration (x) for the linear model (Equation 17)

$$\hat{y} = b_{0w} + b_{1w} x_i \tag{17}$$

   as described in Appendix 1.

3. Iteratively compute the L_C using the method originally proposed by Scott et al.[12] which is the upper 95% confidence 99% coverage tolerance limit for measured concentrations when the true concentration is zero, (Equation 18):

$$\begin{aligned} y_C &= K_{0.95,0.99} s_{L_C} + b_{0w} \\ &= K_{0.95,0.99} a_0 e^{(a_1(y_c - b_{0w})/b_{1w})} + b_{0w} \end{aligned} \tag{18}$$

   where $K_{0.95,0.99}$ is the 95% confidence 99% coverage one-sided normal tolerance limit factor for n observations, where, in this case, n is the total number of measurements (see Table 4.2 in Gibbons[11]). L_C is the corresponding true concentration (Equation 19):

$$L_C = \frac{y_C - b_{0w}}{b_{1w}} \tag{19}$$

   Note that although it is not required for computing the AML, a Currie-type estimate of the DL (L_D) can also be obtained by iteratively computing Equation (20):

$$\begin{aligned} y_D &= y_C + K_{0.95,0.99} s_{L_D} \\ &= y_C + K_{0.95,0.99} a_0 e^{(a_1(y_D - b_{0w})/b_{1w})} \end{aligned} \tag{20}$$

   and L_D is the corresponding true concentration (Equation 21):

$$L_D = \frac{y_D - b_{0w}}{b_{1w}} \tag{21}$$

4. Compute the standard deviation at the L_C from Step 1 (i.e. s_{L_C}), for example (Equation 22):

$$s_{L_C} = a_0 e^{a_1(L_C)} \tag{22}$$

5. Compute the measured concentration at ten times the standard deviation at the L_C (Equation 23):

$$y_Q = 10 s_{L_C} + b_{0w} \tag{23}$$

6. The AML is then computed as Equation (24):

$$x_Q + \left(\frac{t}{b_{1w}} \quad \sqrt{V(y_Q)} \right. \tag{24}$$

where $x_Q = (y_Q - b_{0w})/b_{1w}$. The value t is the upper 99th percentile of Student's t distribution on $n - 2 - p$ degrees of freedom, where p is the number of unknown parameters in the standard deviation model. Alternatively when n is large (e.g. $n > 25$) the AML can be approximated by Equation (25):

$$\text{AML} \sim \left(\frac{x_Q + ts_{y_Q}}{b_{1w}} \right. \tag{25}$$

5.3 Illustration

To illustrate the computation of the AML, return to the data in Figure 1. Inspection of Figure 6 reveals that the Rocke and Lorenzato model fits the observed data quite well. The various steps in the computation are displayed in Table 3. Inspection of Table 3 reveals that the estimated AML is 7.276 ppt and this provides a RSD of 7.78%. Note that a wide range of MLs are possible for these data. For example, spiking at 200 ppt the ML is 153 ppt whereas spiking at 10 ppt yields 6.66 ppt. Both spiking concentrations meet USEPA's 5 : 1 criterion and would therefore represent valid estimates of the ML.

5.4 Alternative Formulations

An alternative that departs somewhat from the AML is to estimate the true concentration that leads to a measured RSD of 10% or 20% or whatever is achievable. Requiring 10% will not always lead to a solution since the rate of change in standard deviation relative to concentration may be greater than 0.1. The solution for the case of nonconstant variance Equation (26) involves iterative solution of

$$y_Q = \frac{1}{r}\sqrt{V(\hat{y}_Q)} \tag{26}$$

where r represents the RSD (e.g. $r = 0.1$ for a 10% RSD). The estimate, referred to as L_Q based on Currie's "determination limit", is then Equation (27):

$$L_Q = \frac{y_Q - b_{0w}}{b_{1w}} \tag{27}$$

Note that here, the RSD is of the predicted measured concentration relative to the standard deviation of the predicted measured concentration, which includes uncertainty in the calibration function. In contrast, for the previous estimators, including the AML, the RSD is computed post hoc in terms of true concentration and as such, will generally be somewhat smaller. When applied to the silver data application of Equations (28) and (29) yields $L_Q = 7.836$ for an RSD of 10% which is quite similar to the AML.

5.5 The Estimator According to Gibbons et al.

Gibbons et al.[27] have provided a direct estimator of L_Q under the assumption that square root transformation of both x and y homogenizes variance.[1] This leads (Equation 28) to the predicted concentration x^*_α for which

$$\hat{y} = \frac{100}{\alpha} s(\hat{y}) \tag{28}$$

the predicted response ($\hat{y}$) that is $100/\alpha$ times its estimated standard deviation ($s(\hat{y})$). Let y^*_α denote the

Step	Equation	Description
1	$S_X = (a_0 + a_1X^2)^{\frac{1}{2}} = (0.285 + 0.00043X^2)^{\frac{1}{2}}$	R−L regression model for standard deviation versus concentration (X); see Figure 6
2	$L_C = KS_X + b_0 = 2.833\ \ S_X - 0.098 = 1.546$	Result of iterative solution for Currie (1968) type critical level or EPRI CMDL
3	$S_{L_C} = (a_0 + a_1L_C^2)^{\frac{1}{2}} = (0.285 + 0.00043 \times 2.389)^{\frac{1}{2}} = 0.535$	Estimated SD at the critical level L_C
4	$L_D = L_C + KS_X = 1.546 + 2.833S_X = 3.1$	Result of iterative solution for Currie (1968) type DL
5	$S_{L_D} = (a_0 + a_1L_D^2)^{\frac{1}{2}} = (0.285 + 0.00043 \times 9.609)^{\frac{1}{2}} = 0.538$	Estimated SD at the DL L_D
6	$Y_Q = 10S_{L_C} + b_0 = 10 \times 0.535 - 0.98 = 5.25$	Averaged measured concentration (or instrument response) at 10 times S_{L_C}
7	$X_Q = (Y_Q - b_0)/b_1 = (5.25 + 0.098)/0.98 = 5.456$	True concentration corresponding to Y_Q, where b_0 and b_1 are the intercept and slope of the recovery equation; see Figure 1
8	$S_{X_Q} = (a_0 + a_1X_Q^2)^{\frac{1}{2}} = (0.285 + 0.00043 \times 29.768)^{\frac{1}{2}} = 0.546$	estimated SD at X_Q
9	$\text{AML} = X_Q + [tS_W/b_1] \times [S_{X_Q}^2 + 1 \quad [1/k] + (X_Q - \overline{X})^2 \quad [(X - \overline{X})^2/K]^{\frac{1}{2}} = 5.456 + [2.402 \times 1.328/0.98] \times [0.298 + 1/71.562 + (5.456 - 14.258)^2/66812.09]^{\frac{1}{2}} = 7.276$	The AML
10	$S_{\text{AML}} = (a_0 + a_1\text{AML}^2)^{\frac{1}{2}} = (0.285 + 0.00043 \times 52.946)^{\frac{1}{2}} = 0.555$	Estimated SD AML
11	$\%\text{RSD} = 100(S_{\text{AML}}/\text{AML})/b_1 = 100(0.555/7.276)/0.98 = 7.78\%$	The RSD at the AML

value of $\hat{y}$ that satisfies Equation (28). Gibbons et al.[27] solved Equation (28) for y_α^* and showed that a good approximation can be obtained as (Equation 29)

$$x_\alpha^* = \bar{x} + \frac{(100/\alpha)s_{y\cdot x} - \bar{y}}{b} \tag{29}$$

$$L_Q = (x_\alpha^*)^2 + 0.632456(x_\alpha^*) \tag{30}$$

also see Gibbons.[11] Gibbons et al. make several observations regarding this estimator. First, they suggest that with small numbers of measurements, $s_{y\cdot x}$ may be a poor estimator of the true population standard deviation $\sigma_{y\cdot x}$ and we may wish to replace $s_{y\cdot x}$ with its upper confidence limit.

Second, the previous definition of $\alpha/100$ times the standard deviation applies to the metric in which the L_Q is estimated. In the present context, a square-root transformation is used to stabilize variance across the calibration line while preserving linearity of the function. An RSD of 10% in this transformed response metric actually corresponds to a 20% RSD in the raw concentration metric. Therefore, obtaining a 10% RSD in the metric of measured concentrations would require a 5% RSD in the transformed response scale.

Application of this estimator to the silver data yields an L_Q of 22.159 $\mu g\,L^{-1}$ for a 10% RSD in the transformed metric. This value is somewhat higher than the previous estimators indicating that in this example, the square-root transformation failed to bring about constant variance at the lowest concentrations.

6 DISCUSSION

Perhaps the most significant contribution of this work is to demonstrate that the most critical source of bias in

estimating limits of detection and quantification is the effect of nonconstant variance. Results presented here reveal that a myriad of DL estimates can be obtained from exactly the same data and analytic method solely as a function of the concentration at which samples are spiked. The only solution in this case is to base limits of detection on multiple-concentration calibration data and either directly model association between variability and concentration or use a variance-stabilizing transformation.

In the calibration setting, four general DL estimators are described and the four methods appear to give reasonably similar results, at least in the example considered here. This finding indicates that we pay a very small price for considerable generality by adopting a tolerance interval-based approach that will cover 99% of all future detection decisions compared to only a single future detection decision. Similar results were found for calibration-based quantification limit estimators.

Despite the guidance provided by this developing literature on analytical detection decisions, USEPA continues to base regulations on the MDL or, for cases in which quantifiable measurements are required, a simple multiple of the MDL (i.e. the ML). As illustrated here, this practice can lead to bias, most notably an extreme dependence on the selection of spiking concentration. Despite some guidance on selection of spiking concentration, actual practice is guided by demonstrating compliance with published standards rather than using the true analytical capabilities of the laboratory. For example, MDLs are routinely determined in laboratories by spiking as many as 70 constituents at a fixed concentration in each of seven replicate samples. In this way it is impossible to iteratively adjust each constituent's concentration in the way suggested by USEPA. In contrast, if calibration-based methods were used, USEPA could designate the range of concentrations in advance to insure that the computed MDL is not adversely affected by a poor selection of initial spiking concentration. In future, USEPA should consider calibration-based approaches for determining limits of detection and quantification.

ABBREVIATIONS AND ACRONYMS

AML	Alternative Minimum Level
DL	Detection Limit
IDL	Instrument Detection Limit
MCL	Maximum Contaminant Level
MDL	Method Detection Limit
ML	Minimum Level
PMDL	Practical Method Detection Limit
RSD	Relative Standard Deviation
ULS	Unweighted Least Squares
USEPA	United States Environmental Protection Agency
WLS	Weighted Least Squares

APPENDIX 1

Details of the WLS prediction interval approach described by Oppenheimer[23] are provided in the following. To obtain the Hubaux–Vos result set all weights $k_i = 1$. To obtain a DL based on tolerance intervals see equation 5.3.2 in Gibbons[11] and Zorn, Gibbons and Sonzogni.[31]

Compute the WLS regression[32] of measured concentration or instrument response (y) on true concentration (x) for the linear model

$$\hat{y}_{wi} = b_{0w} + b_{1w}x_i \tag{31}$$

where

$$b_{1w} = \frac{\sum_{i=1}^{n}[(x_i - \bar{x}_w)y_i/k_i]}{\sum_{i=1}^{n}[(x_i - \bar{x}_w)^2/k_i]} \tag{32}$$

$$b_{0w} = \bar{y}_w - b_{1w}\bar{x}_w \tag{33}$$

$$\bar{y}_w = \frac{\sum_{i=1}^{n}[y_i/k_i]}{\sum_{i=1}^{n}[1/k_i]} \tag{34}$$

$$\bar{x}_w = \frac{\sum_{i=1}^{n}[x_i/k_i]}{\sum_{i=1}^{n}[1/k_i]} \tag{35}$$

and the weight $k_i = s^2_{x_i}$ is the variance for sample i (Equations 31–35). The weighted residual variance is (Equation 36):

$$s^2_w = \frac{\sum_{i=1}^{n}[(y_i - \hat{y}_{wi})^2/k_i]}{n-2} \tag{36}$$

and the estimated variance for a predicted value $\hat{y}_{wj}$ is (Equation 37):

$$V(\hat{y}_{wj}) = s^2_w \quad k_j + \frac{1}{\sum_{i=1}^{n}(1/k_i)} + \frac{(x_j - \bar{x}_w)^2}{\sum_{i=1}^{n}[(x_i - \bar{x}_w)^2/k_i]} \tag{37}$$

where k_j is the estimated variance at concentration x_j. An upper $(1-\alpha)100\%$ confidence interval for $\hat{y}_{wj}$ (i.e. a prediction interval for a new measured concentration or instrument response at true concentration x_j) is (Equation 38):

$$\hat{y}_{wj} + t\sqrt{V(\hat{y}_{wj})} \tag{38}$$

where t is the upper $(1-\alpha)100$ percentage point of Student's t distribution on $n-2$ degrees of freedom[12,18]. The WLS estimate of L_C is therefore (Equation 39):

$$L_C = \frac{ts_w}{b_{1w}} \quad \overline{s^2_{L_C} + \frac{1}{\sum_{i=1}^{n}(1/k_i)} + \frac{(L_C - \bar{x}_w)^2}{\sum_{i=1}^{n}[(x_i - \bar{x}_w)^2/k_i]}} \tag{39}$$

and the WLS estimate of L_D is (Equation 40):

$$L_D = L_C + \frac{ts_w}{b_{1w}} \quad \overline{s^2_{L_D} + \frac{1}{\sum_{i=1}^{n}(1/k_i)} + \frac{(L_D - \bar{x}_w)^2}{\sum_{i=1}^{n}[(x_i - \bar{x}_w)^2/k_i]}} \tag{40}$$

Note that in order to compute L_C and L_D we must have estimates of $s^2_{L_C}$ and $s^2_{L_D}$ which are often unavailable and must be estimated using a model of standard deviation versus concentration, for example an exponential model[28] of the form (Equation 41):

$$s_x = a_0 e^{a_1 x} \tag{41}$$

or the model suggested by Rocke and Lorenzato[29] which reduces to (Equation 42):

$$s_x = \sqrt{a_0 + a_1 x^2} \tag{42}$$

both of which can be fitted by nonlinear least squares and require iterative solution. Gibbons et al.[10] suggest a noniterative approximation based on the assumption that variance is proportional to concentration. This assumption leads to the WLS estimates Equations (43–45):

$$b_{0w} = \frac{\sum_{i=1}^{n}(y_i/x_i)\sum_{i=1}^{n}x_i - n\sum_{i=1}^{n}y_i}{\sum_{i=1}^{n}(1/x_i)\sum_{i=1}^{n}x_i - n^2} \tag{43}$$

$$b_{1w} = \frac{\sum_{i=1}^{n}(1/x_i)\sum_{i=1}^{n}y_i - n\sum_{i=1}^{n}(y_i/x_i)}{\sum_{i=1}^{n}(1/x_i)\sum_{i=1}^{n}x_i - n^2} \tag{44}$$

and

$$s^2_w = \frac{\sum_{i=1}^{n}(y_i^2/x_i) - b_0\sum_{i=1}^{n}(y_i/x_i) - b_1\sum_{i=1}^{n}y_i}{n-2} \tag{45}$$

To compute L_C we can set the weight equal to the lowest nonzero concentration $x_{\min}$ (Equation 46):

$$L_C = \frac{ts_w}{b_{1w}} \quad \overline{x_{\min} + \frac{1}{n} + \frac{(x_{\min} - \bar{x})^2}{\sum_{i=1}^{n}(x_i - \bar{x})^2}} \tag{46}$$

To compute L_D we can set the weight equal to L_C (Equation 47):

$$L_D = L_C + \frac{ts_w}{b_{1w}} \quad \overline{L_C + \frac{1}{n} + \frac{(L_C - \bar{x})^2}{\sum_{i=1}^{n}(x_i - \bar{x})^2}} \tag{47}$$

Given current computing environments, however, there is no reason why the iterative solution should not be performed i.e. simple repeated substitution beginning from $L_C = 0$ and $L_D = L_C$ until convergence (i.e. change of less than 10^{-4} in estimates of L_C and L_D on successive iterations).

*A dioxin-like compound (DLC) is a halogenated aromatic compound that has toxicological properties similar to those of the reference toxicant 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). The DLCs include other halogenated dibenzo-*p*-dioxins and dibenzofurans (especially those that are chlorinated in the 2-,3-,7-, and 8-positions), and coplanar polychlorinated biphenyls (PCBs). They associate with the aryl hydrocarbon receptor (AhR) protein, and share some biological end-points with TCDD, notably the induction of Phase 1 monooxygenase enzymes. Because DLCs normally occur as complex mixtures in environmental and biological samples, it is common to refer to the TCDD equivalent concentration [toxic equivalence (TEQ)], which is obtained by summing for each congener its actual amount or concentration by an empirical toxic equivalency factor (TEF). Conventional analysis of DLCs by gas chromatography/mass spectrometry (GC/MS) is cumbersome and expensive, and much attention has been given to developing bioassays that will yield a measure of the TEQ in a single determination. Many such bioassays are mechanism-based, meaning that the assay end-point is one of the steps along the pathway of the mechanism of action.*

This article begins with an overview of bioassay methods in general, pointing out similarities and differences between chemical assays and bioassays, before describing particular assays that have been developed for DLCs. Among mechanism-based assays, AhR binding assays are well established, and are useful because they include the dioxin-like activity of both productive and unproductive compounds. In assays based on subsequent stages of the mechanism of action, unproductive substances can antagonize the responses of productive compounds, a phenomenon that is explicable in terms of target molecule antagonism, in which the AhR protein is the target molecule.

Immunoassays for DLCs have recently received much attention; although their spectrum of cross-reactivity does not always correlate well with TEFs, there has been important recent progress in terms of the sensitivity and detection limit (DL) of these assays. Finally, early life stage bioassays are becoming increasingly important as research has revealed the toxicological effects of DLCs during development.

1 INTRODUCTION

1.1 Dioxin-like Compounds Defined

The term ''DLC'' is applied to compounds having toxicological properties similar to the reference toxicant TCDD. DLCs are halogenated aromatic compounds that bind to the AhR protein, or that cause overt toxic and biochemical end-points similar to those of TCDD, as will be discussed in section 1.4. DLCs include other polychlorinated dibenzo-*p*-dioxin (PCDD) compounds (especially those that are chlorinated in the 2-,3-,7-, and 8-positions: Figure 1), the corresponding polychlorinated dibenzofuran (PCDF) compounds, bromo- and bromochloro-substituted dibenzo-*p*-dioxins and dibenzofurans, and coplanar PCBs. Many polycyclic aromatic hydrocarbons (PAHs) also associate with the AhR protein, and share some biological end-points with TCDD, notably the induction of Phase I monooxygenase enzymes.

The organization of this article is as follows. The Introduction describes bioassay methods in general, and includes a brief discussion of the mechanism of toxic action of TCDD, on account of our bias towards mechanism-based assay methods. Subsequent sections address sequential steps along the mechanism of toxic action that have been used to develop assays for DLCs. These are followed by a brief discussion of immunoassays (which are not directly mechanism-based) and assays based on overtly toxic end-points such as early life stage and cell proliferation bioassays.

Figure 1 General chemical structures and numbering system for several DLCs.

1.2 Chemical Assay: Toxic Equivalents

The standard chemical method of analyzing DLCs is labor intensive, and therefore expensive. After spiking with an isotopically labeled recovery standard such as [$^{13}C_{12}$]TCDD, sample preparation involves solvent extraction and multiple chromatographic procedures to isolate the PCDD/PCDF fraction. Quantitation of individual PCDD and PCDF congeners is achieved by capillary gas chromatography/high-resolution mass spectrometry (MS),[1,2] giving the concentration of each congener in units such as nanograms of congener per gram of sample.

Chemical analysis cannot provide biological information such as an estimate of a sample's toxic potency. One such measure, the TEQ, is obtained from analytical data by the use of a TEF, that relates the potency of DLC X to that of the reference toxicant TCDD, whose TEF = 1. TEFs are not precisely defined parameters, but are based on a consensus of relative potency, considered over a wide range of end-points and species; the size of the available database varies from congener to congener. The TEQ of a sample is given by [(concentration of X) × (TEF of X)]. In the commonly used I-TEF scheme,[3] TEFs are available for the 17 ''most toxic'' PCDD and PCDF congeners that are chlorinated in the 2-,3-,7-, and 8-positions, and provisional TEFs have been proposed for the coplanar PCB congeners.[4] The potencies of different DLC congeners vary greatly, as do their relative concentrations in environmental samples. For example, the concentrations of coplanar PCBs in many animal tissues have been found to be orders of magnitude higher than those of PCDD/PCDFs,[5,6] making the PCBs major contributors to the TEQ of a sample, despite their small TEF values.

The TEQ approach is inherently cumbersome, because a unique TEF must be assigned to each DLC, in order to include its contribution to the calculated potency. The TEQ will be underestimated if the sample contains DLCs for which no TEF has been established, and the more congeners to be assessed, the greater are the complexity of analytical separation and the cost of analysis. Another problem is that the TEQ obtained by GC/MS may not afford an optimal measure of the potency of a sample towards a particular end-point: potency rankings of DLC congeners vary with the end-point and species examined, and not all DLCs produce all end-points. A third problem is that the TEF approach explicitly takes the TEQ of a complex sample to be the sum of the contributions of its components, assuming an additive response to a complex mixture of DLCs (no synergism or antagonism). Putzrath[7] has questioned the assumption of additivity in the TEF approach from a different perspective. He argues that for parallel log dose–response curves (as is common for DLCs) the relative concentrations of toxicants X and Y needed to produce equal large responses are different from the relative concentrations needed to produce equal small responses. The apparent TEF of a given DLC relative to TCDD will therefore vary according to the position on the dose–response curve, and so considerable inaccuracies might result when TEFs derived from high-dose laboratory studies are used to extrapolate to low-dose environmental exposure.

1.3 Bioassays

We define a bioassay as a technique whose end-point is attained through the use of either living organisms or biological materials (e.g. tissues, enzymes, or antibodies). Detection of the end-point signals qualitatively the presence of the analyte, while the intensity of the response is used to quantitate the analyte, as in conventional chemical analysis. In either case, the assay end-point must be calibrated against the concentration of the analyte. In vivo bioassays employ living animals or plants. In vitro methods can utilize living cells, such as bacteria or cultures of animal or plant cells, or they can use isolated tissues, such as liver slices excised from a whole animal. They may also employ subcellular fractions, such as microsomes, chloroplasts, or cytosol, or preparations containing or comprising specific biomolecules such as receptors, enzymes, or nucleic acids. The latter bioassays are hardly different from chemical assays, and many of them use conventional chemical detection techniques such as absorption or fluorescence spectroscopy. One recently developed assay for DLCs, for example, employs the firefly luciferase gene that has been genetically engineered into bacterial and yeast cells (section 2.2.2). In this assay, the measured parameter is light emission catalyzed by luciferase, detected by a photomultiplier tube that records and quantitates light intensity. Likewise, an enzyme-linked immunosorbent assay (ELISA) relies on an enzyme that catalyzes the formation of a product

that can be quantitated by techniques such as absorption or fluorescence spectroscopy (section 3). The quantity of the product of the enzymatic reaction is proportional to the amount of the antigen–antibody (Ab) complex that was formed.

The cost of analysis generally decreases in the order in vivo assays > in vitro assays with whole cells > in vitro assays with subcellular fractions, but so does the biological relevance of the assay end-point in terms of human health or environmental risk assessment. Animal assays increase in cost with the type of organism (invertebrates < fish < rodents < primates) and with the length of time that is needed for the results to manifest themselves (acute toxicity tests < carcinogenicity tests < multigenerational reproductive tests). Although the use of in vitro assays with bacteria or immortalized cell lines avoids the use of live animals, biological relevance requires some in vivo animal testing when the final objective is human health or environmental risk assessment. Even if an in vivo bioassay replicates the actual toxic end-point, laboratory animals must be used as surrogates when humans are the target organism of concern. Extrapolation of results obtained with laboratory animals to humans is difficult because of the varying susceptibilities of different species and strains towards intoxication by DLCs.[8]

Unlike chemical assays, many bioassays monitor *function*, and have little or no diagnostic capability for identifying the agent responsible for causing the effect. For example, the acute toxicity of industrial effluents may be monitored by means of the 96 h rainbow trout test or the 24 h *Daphnia magna* test, both of which employ single organisms as surrogates for aquatic species in general. From a regulatory perspective, the lack of diagnostic information is immaterial, since what is required is knowledge of whether or not the effluent is acutely toxic; the identity of the toxicant can be ascertained in a follow-up study, if it is not already known. Other effects such as developmental toxicity in aquatic organisms can also be conveniently studied in this way (see section 4). Similar considerations apply to testing new drugs or pesticides for effects such as carcinogenicity or teratogenicity; in such cases, the identity of the substance is known, and what is required is quantitative information about its possible adverse biological effects.

Bioassays with live organisms or cell cultures, enzyme assays, and immunoassays monitor overt end-points that are different from the end-point of interest to environmental or human health, and a correlation must then be drawn between the surrogate end-point and the end-point of interest. Acute toxicity tests such as the LD_{50} have often been used, incorrectly, as a measure of the toxic potencies of substances towards chronic exposures. This is particularly inappropriate for DLCs, which cause lethality by mechanisms different from those involved in other end-points.[9]

Figure 2 Plot of response intensity vs analyte concentration demonstrating the nonlinear curve obtained when the response is saturable, as is the case in most bioassays.

Many issues concerning the applicability of bioassays are fundamental questions associated with any analytical procedure, such as the shape of the dose–response curve and its limits of quantitation. Consider a generic calibration curve such as that shown in Figure 2. Parameters of analytical importance include its shape (linear or nonlinear) and slope (calibration sensitivity), the range of analyte concentrations over which the calibration curve is valid, reproducibility, and the DL. In chemical analysis, the DL is frequently defined as the response that is three standard deviations away from that of the "blank".[10] The analyte concentration at the DL is given by $c_{DL} = 3 \times s_{bl}/S$, where s_{bl} is the standard deviation of the blank and S is the calibration sensitivity. The ideal analytical procedure has a linear calibration curve over a wide dynamic range and has a large slope, permitting a low DL. The foregoing parameters are mutually dependent: linear responses have inherently wider dynamic ranges than responses whose calibration sensitivities fall progressively with increasing analyte concentration. Low DLs require techniques that have large calibration sensitivities (i.e. a small amount of analyte produces a response that is significantly different from a blank) and/or high precision, implying reproducibility and a small standard deviation of the measurements. Chemical analysts also seek procedures that have high specificity for the analyte of interest, implying no interference by other analytes but, as noted already, this is often not possible with bioassays.

A wide dynamic range is rare with in vitro bioassays, and is impossible for in vivo bioassays, because the response is saturable. In acute lethality or teratogenicity assays, for example, there will be some concentration

of analyte above which essentially all the individuals die or are born with birth defects. Consequently, it is impossible for the response to increase further, and so $S \rightarrow 0$ at high analyte concentration. Moreover, the experimental uncertainties are usually larger than in physical techniques, because of biological variability among individuals in the groups being tested, even when using inbred strains of organisms of the same sex, age, and weight. At the lower limit of quantitation, a relatively high concentration of analyte may be needed to achieve a response (the lowest observed effect level) that differs in a statistically significant way from that of the unexposed group.

A particular difficulty arises with respect to the carcinogenicity of DLCs. TCDD is a weak carcinogen in laboratory animals such as rats[11] and a disputed human carcinogen.[12] The linear models for extrapolating cancer incidence from experimentally observable doses to the low doses associated with occupational or environmental exposure assume no threshold for the response.[13] Regulators may define the dose corresponding to a standard such as one excess cancer in 10^6 lifetimes [e.g. Sielken[14]], as corresponding to risks that might be acceptable to most members of society. Such a response intensity corresponds to concentrations of DLCs that are far below the lowest observed effect level in a bioassay, and a long extrapolation is inevitable.

The foregoing factors mean that quantitative data can rarely be obtained from in vivo bioassays over a range of more than about one order of magnitude. Calibration curves such as Figure 2 are therefore not generally used to evaluate in vivo bioassays; instead an approach such as the analysis of variance (ANOVA) may often be used to give information about whether the various treatment groups are statistically different from each other and from controls. A more appropriate presentation of the data is a histogram such as Figure 3 rather than the continuous function implied by Figure 2.

Another analytical question is whether an assay affords *diagnostic* information as well as quantitative information; in other words, whether the parameter being monitored identifies the analyte. Bioassays usually have little diagnostic capability in comparison with chemical methods of analysis such as nuclear magnetic resonance (NMR) and MS, although, as already noted, this may be irrelevant for a functional bioassay.

Important applications for DLC bioassays include environmental remediation programs, which usually require the screening of large numbers of samples to determine which sites require remediation, or to monitor the progress of cleanup. In these samples, the analytes must be extracted from matrices such as soil, sediment, and biota. The extent of pretreatment (cleanup) of the sample that is needed before the assay can be applied

Figure 3 An example of bioassay data presented as a histogram.

is a major consideration, because much of the cost of conventional chemical analysis for DLCs is associated with the lengthy cleanup of the sample prior to analysis by GC/MS. Monitoring or screening assays are of limited use unless a major portion of the cleanup effort can be avoided (e.g. Höckel et al.;[15] Schwirzer et al.;[16] Hu et al.[17]). This issue is often not addressed by the advocates of new bioassays.

Mixtures of compounds present further difficulties in bioassays compared with chemical analysis. A major problem in chemical assays is interference between the responses of different analytes. For example, the mass, infrared (IR), and NMR spectra of mixtures are generally uninterpretable, because the analyst cannot confidently assign the peaks to the correct analytes. This difficulty is overcome by the use of linked methods such as GC/MS that combine the resolving power of chromatography with the diagnostic capability of spectroscopic methods. By contrast, the response in a bioassay is due to the whole sample rather than individual analytes, and the activity can be calibrated against the response of a standard substance. Assays for DLCs are normally calibrated against TCDD, and the response of the sample is reported in TCDD equivalents, i.e. the dose of TCDD that would cause the same response intensity. This approach inherently assumes additive behavior of the mixture's components, without synergism or antagonism of the biological response. Synergism leads to an overestimation of the concentration of the analyte, but is rarely encountered. Antagonism, which is fairly common, can underestimate the concentration of the analyte to the point of a false negative (the sample mistakenly appears to be uncontaminated).

In vivo antagonism can occur by numerous mechanisms that are difficult to differentiate; the situation in vitro is usually less complicated. A common situation is that the

analyte and the antagonist compete for a limited amount of a target biomolecule, such as a receptor or an enzyme; the analyte is processed and leads to the normal biological response or enzyme product, but the antagonist does not get processed. An agonist is a substance that elicits the toxic or biochemical end-point under study, whereas an antagonist blocks or masks the biological activity of an agonist. When administered on its own, such a substance is better described as unproductive rather than as an antagonist.

Antagonism of this sort (target molecule antagonism) is seen only at high concentrations of analytes (agonist with or without antagonist), at which most of the active sites on the target molecule are occupied. At low total occupancy of the target molecule, the unproductive molecule can occupy vacant target molecules without displacing the agonist, and no inhibition of the assay end-point is seen; conversely, at high total occupancy, the unproductive occupation of target molecules by the antagonist can occur only by displacing the agonist. This phenomenon has been seen in teratogenicity studies in which pregnant mice are administered TCDD, with and without coadministration of PCBs.[18] At high doses of TCDD, coadministration of PCBs antagonizes the teratogenic response, owing to occupation of the AhR target molecule by the nonteratogenic PCBs; antagonism is not seen at low doses of TCDD, at which receptor occupancy is incomplete.

Although a bioassay for DLCs can give a numerical estimation of the TEQ of the sample as a whole, relative to the reference toxicant TCDD, it is unlikely that regulatory decisions could ever be based solely on the results of such assays owing to the lack of diagnostic information about the analyte(s). Lesnik[19] has identified several regulatory issues in the context of using immunoassays, but his comments apply equally to other bioassays. The concerns include extraction efficiency and comparison of assay results with those from previously validated procedures, the occurrence of false negatives and false positives, and cross-reactivity with other analytes. These will be discussed in turn.

Extraction efficiency is difficult to monitor even when a recovery standard is used, because this added surrogate may be more easily removed from the matrix than endogenous DLCs. The practice of adding a surrogate, such as [$^{13}C_{12}$]TCDD in chemical analysis by GC/MS, is impractical in bioassays, because the surrogate would itself be a DLC and thus contribute to the assay. In principle, the surrogate could be used in the standard addition mode,[20] but this seems not to have been tried in practice. As for validation against other procedures, few proposed assays for DLCs have been rigorously tested in this way (e.g. Zacharewski et al.[21]). Ideally, the assay should require the minimum of extraction and other work-up, to save on analysis time (for a discussion and example, see Hu et al.[17])

False negatives and false positives: a major application of dioxin bioassays involves screening samples for activity and determining which are below and which above a consensus cut-off TEQ, so that only those samples assaying above the cut-off are taken to detailed chemical analysis. False positives occur when an interfering, but not dioxin-like, substance can evoke the end-point being monitored; to this extent, false positives make the bioassay conservative because the sample's contamination is overestimated. False positives increase the number of samples that must be subjected to confirmatory analysis; a high rate of false positives negates the benefit of a low-cost bioassay. False negatives, on the other hand, suggest that contaminated samples are clean; from a regulatory viewpoint, any significant occurrence of false negatives is unacceptable. False negatives are most likely to occur if a relatively nontoxic congener masks or antagonizes the activity of a more potent congener.

Cross-reactivity in bioassays would be a problem if one wished to monitor the concentration of a single DLC (e.g. TCDD). Realistically, bioassays for DLCs will be applied to assessing the TEQ of a sample; cross-reactivity is advantageous if each DLC behaves additively in the assay and if the responses of different DLCs match their TEFs reasonably well. Immunoassays for dioxins in environmental samples exhibit cross-reactivity; it is usually possible to predict the types of structures will cross-react, but the real question is whether the TEQ determined by a particular assay reflects the toxic potency of the sample. Bearing this in mind, we state here our prejudice for *mechanism-based bioassays*: those that use a point along or minimally divergent from the established metabolic pathway leading to toxicity as the indicator of potency.

1.4 Toxicity and Mechanism of Action of Dioxin-like Compounds

Most of our knowledge of the toxicity of DLCs is based on that of TCDD, which elicits numerous toxic responses. In addition to the widely reported acute lethality, which occurs at very low doses and proceeds via a wasting syndrome, other effects include reduced immunocompetence, hyperplasia, carcinogenicity, developmental toxicity (including teratogenicity and errors in sexual differentiation), and altered porphyrin metabolism. TCDD does not induce all effects in all species, and evidence is lacking that all effects are exhibited by all DLCs (for reviews, see Landers and Bunce;[22] Whitlock;[23] Okey et al.;[24] Mukerjee;[25] DeVito and Birnbaum[26]).

The complexity of biological responses to TCDD, and extremely limited knowledge about other DLCs and DLC mixtures, make it difficult to assess the toxic potential of

Figure 4 Schematic representation of the mechanism of action of DLCs. A ligand (L) enters the cell and binds to the aryl hydrocarbon receptor ligand binding subunit (ALBS) of the cytosolic AhR. The receptor undergoes transformation/activation, nuclear translocation, and dimerization with the aryl hydrocarbon receptor nuclear translocator protein (ARNT), following which it binds to dioxin response enhancers (DREs), resulting in the induction of cytochrome P450 1A1 and a variety of other proteins. The numbers indicate the stages in this mechanism on which bioassays can be based: (1) receptor–ligand binding; (2) receptor transformation and activation; (3) nuclear translocation; (4) DNA binding; and (5) enzyme induction.

environmental samples, which usually contain complex mixtures of DLCs. Combustion by-products such as fly ash contain a wide range of PCDDs and PCDFs,[27] while biota such as fish, meat, and milk contain a large number of organochlorines. Among the latter, PCDDs and PCDFs are usually minor constituents in comparison with PCBs, at least some of which are dioxin-like, and organochlorine pesticides such as DDT, that in general are not. Among DLCs, PCDDs, PCDFs, and coplanar PCBs combine toxicity with environmental persistence, and their lack of chemical and metabolic reactivity allows them to bioaccumulate through food webs. Other compounds such as partly methylated PCDDs and PCDFs[28] and the chlorinated azobenzenes are of less concern because they are metabolized more rapidly.

Mechanism-based bioassays utilize current knowledge about the mechanism of action of the toxicant, by exploiting a biochemical event in the mechanism of action as an assay end-point from which to estimate the TEQ. The closer the relationship between the biochemical event being monitored and the toxic end-point of interest, the greater is the biological relevance of the assay. The mechanism of action of TCDD as it is currently known is summarized in Figure 4. As already noted, the behavior of other DLCs is generally assumed to be similar.[22,24,29]

Step 1. TCDD is believed to enter cells by passive diffusion: as a lipophilic substance it has a high affinity for the lipid bilayers constituting the plasma membrane, and bioconcentrates in adipose tissue.[30] The biochemical target of TCDD in vertebrates is the AhR protein, so named because it was first detected as a binding protein for certain aromatic hydrocarbons. Most, if not all, biochemical effects of TCDD are AhR-mediated i.e. association of TCDD with the receptor is a necessary precondition for toxicity. The AhR is an oligomeric ~280 kDa protein complex found in the cytosolic fraction

of tissue preparations. It contains an ALBS with molar mass 90–120 kDa, depending on the species,[31] and a molecule of the 90 kDa heat shock protein (hsp90), which is thought to mask the DNA-binding site[32] and keep the receptor in a conformation that can bind the ligand.[33] Association of the AhR with hsp90 is required to maintain functional signal transduction.[34] The remaining composition of the cytosolic AhR has not been elucidated, but evidence exists that it may contain a molecule of the tyrosine kinase c-src[35] and/or the 38 kDa hepatitis B virus X-associated protein 2 (XAP-2).[36]

The susceptibility of animal strains to intoxication by TCDD correlates with the affinity of TCDD for the AhR. In highly susceptible animals such as the C57BL/6 mouse, estimates of the association constant are $>10^{11}\,M^{-1}$;[37,38] less susceptible strains such as the DBA/2 mouse have a lower affinity form of the AhR.[39,40] The human form of the AhR also has low affinity for TCDD.[41–43] Binding affinity to the AhR has long been used to identify substances that might exhibit dioxin-like activity.[44] Numerous correlations, beginning with those published by Poland et al.,[45] and continuing with quantitative structure–activity relationship (QSAR) studies through the 1980s, showed an approximate rank ordering between receptor binding affinity and enzymatic or overtly toxic end-points. These provided the basis for the accepted paradigm that the toxicity of DLCs is AhR mediated.[29,46,47]

The AhR preferentially binds lipophilic molecules of the size and shape of TCDD [planar, molecular dimensions ca. 1.0×0.3 nm[45]]; the poorer the fit between the DLC and the receptor binding site, the lower is the affinity (Figure 5). Much thought has been given to the natural role of the AhR and to finding endogenous ligands for it. One possibility is binding to foreign substances such as PAHs and indole-3-carbinol (present in cruciferous vegetables),[48] leading to induction of elevated levels of monooxygenase enzymes that metabolize the foreign substances. Other endogenous compounds that have been demonstrated to bind and activate the AhR are tryptophan and tryptophan metabolites[49] and the heme degradation products bilirubin and biliverdin.[50] It is a reasonable but unproven supposition that many of the toxic responses of DLCs may result from altering the intracellular levels of monooxygenases, which are powerful oxidants. The AhR may also be a regulatory protein that controls the expression of many unrelated genes,[24]

Figure 5 The dimensions of TCDD.

which changes the focus of the mechanism of intoxication from monooxygenase enzyme induction to the activation of c-src and the activation of a kinase cascade.

Step 2. Following association with a ligand such as TCDD, the AhR–ligand complex undergoes a poorly understood process termed transformation, which is temperature- and species-dependent. Immunoprecipitation experiments have shown that AhR subunits are released at this stage,[34,51,52] leaving behind free ALBS in the form of its TCDD complex. Although the initially formed AhR–TCDD complex can release its ligand, TCDD is bound almost irreversibly, although not covalently, following transformation. This suggests that a significant conformational change in ALBS accompanies transformation, and that the role of hsp90 may be to act as a molecular chaperone, maintaining ALBS in a conformation that can bind ligand.[52] An ambiguity exists in older literature reports of ligand binding affinity to the AhR, because it is unclear whether the untransformed or transformed AhR–ligand complex was the species present after incubation of the ligand and the receptor preparation.

Step 3. The transformed ALBS–TCDD complex penetrates the nuclear membrane, where it heterodimerizes with the ARNT through basic helix–loop–helix motifs.[53,54] Phosphorylation may occur at this stage, following which heterodimers bind to recognition elements on DNA known as DREs.[55] The term *enhancer* reflects the *increase* in the expression of gene products following exposure to substances such as TCDD. DRE binding with TCDD occurs with high affinity.[56,57] Several DREs have been identified, and are characterized by similarity of their nucleotide sequences. In vitro binding experiments have been carried out with oligonucleotides containing the consensus sequence.

Steps 4 and 5. The DREs appear to act as genomic switches, initiating the transcription of mRNAs, which in turn yield the appropriate protein gene products.[23] Transcription of *CYP 1A1* (cytochrome P-450 1A1 mRNA) begins within a short time of exposure to TCDD, and all necessary components appear to be present constitutively, provided that the cells possess functional AhR and ARNT. The exact mechanism of regulation is not yet completely understood; a very recent suggestion is that the liganded AhR complex activates gene expression of a repressor protein that competes with ALBS for binding ARNT, thereby permitting down-regulation of AhR response subsequent to activation.[58] Past speculation has focused on the induction of a plethora of gene products that lead to different toxicological responses; the only well-characterized pathway, however, is monooxygenase enzyme induction. The recognition of the tyrosine kinase pathway suggests that the latter may be responsible for other biological responses to DLC exposure.

One use of mechanism-based bioassays is to follow a particular DLC stepwise through its mechanism of action to determine whether it acts as an agonist or as an antagonist at each step. Consider the case of two substances that both bind the AhR, only one of which induces CYP 1A1. An agonist not only binds the AhR, but successfully surmounts all subsequent hurdles leading to induction of the enzyme; its antagonist may bind the AhR, thereby reducing the stock of AhR molecules available to bind the agonist, but will not necessarily give a positive result at each subsequent step. The use of a series of assays, step by step in the mechanism, can allow the investigator to probe the exact mechanism of action of such compounds. For example, in the case of AhR binding assays, not all substances that bind to the AhR are necessarily toxic, as is clearly demonstrated by indole-3-carbinol[59,60] and certain nonplanar PCBs such as 2,2′,4,4′,5,5′-hexachlorobiphenyl (PCB 153). These compounds are active in an AhR binding assays, but do not cause dioxin-like toxicity because they undergo the subsequent association with DRE only inefficiently.[61]

2 MECHANISM-BASED ASSAYS

2.1 Receptor–Ligand Binding Assays

Receptor–ligand binding assays are employed in mechanistic biochemistry and toxicology to assess the relative binding affinity (RBA) of ligands, in order to define parallels between RBA and biological potency. They can also be used to assess TEQ, by determining the amount of TCDD with the same affinity for a known aliquot of AhR as the test substance or mixture. Binding affinity can be determined by means of a saturation assay or a competition assay.

2.1.1 Saturation Assays

In a saturation assay, increasing concentrations of the test substance (ligand) are incubated with a fixed amount of AhR, giving increasing amounts of bound ligand. An experimental complication in AhR–ligand binding assays is that the concentration of AhR in cells is so small [about 10^5 receptors per cell[29]] that the concentrations of the liganded and unliganded protein cannot be measured directly. The traditional approach is to use a radiolabeled ligand such as [^{3}H]TCDD; the parameter that is actually measured is the concentration of radiolabeled receptor–ligand complex obtained following incubation of the receptor preparation and the ligand(s).

For saturation binding assays using radioligands, the desired measurement is the concentration of AhR bound to the radioligand. The principle is that the ligand can bind specifically to saturable, high-affinity sites on the receptor, and nonspecifically but with low affinity to other sites on the receptor or on other proteins. Two determinations must be made. The first is to incubate a fixed amount of the receptor preparation with increasing concentrations of radiolabeled ligand, and measure the concentration of receptor–ligand complex (''total binding''). In the second determination, the experiment is repeated with a large (e.g. 200-fold) excess of unlabeled ligand in addition to the radioligand to measure nonspecific binding. The specific binding is the difference between the two measurements. For the assay to be accurate the ligands must be present in excess over the saturable sites (at the highest concentrations) but not in excess over the nonspecific sites.

Saturation assays involving radioligands are usually analyzed by the method of Scatchard,[62] which assumes that the concentration of unliganded receptor (R) is at all times represented by the difference between the initial, total receptor concentration (R_0) and the concentration of specifically bound receptor–ligand complex (RL) [Equation 1]:

$$[R] = [R]_0 - [RL] \tag{1}$$

Under these conditions, Equation (2) gives the relationship between K_d, the dissociation constant of the receptor–ligand complex, and the concentration of the radioligand (L):

$$\frac{[RL]}{[L]} = \frac{[R]_0}{K_d} - \frac{[RL]}{K_d} \tag{2}$$

From a plot of [RL]/[L] vs [RL], the slope gives K_d and the intercept affords the total concentration of specific binding sites.

Unfortunately, the Scatchard method is inapplicable to the AhR assay under most conditions, because the unliganded receptor is very susceptible to thermal inactivation of its binding capability. This means that $[R] < ([R]_0 - [RL])$ and, as a result, K_d is overestimated, often by several orders of magnitude.[63] Previous experiments in our laboratory[38] have shown that it is possible to estimate K_d from kinetic experiments, even in the presence of thermal inactivation of the receptor. The method is, however, cumbersome and inaccurate, because the rate constants for both receptor–ligand association and complex dissociation must be fitted to the time course of complex formation.[64]

The whole-cell binding assay reported by Dold and Greenlee[65] has been developed to screen cell culture lines for their AhR content, rather than screening different samples for their DLC content. In this assay, the cells are incubated with radiolabeled TCDD (with

and without unlabeled competitor), and after appropriate manipulations the cells are counted for their radioactivity. Uptake of radioligand is observed only for cell lines having a functional high-affinity AhR.

2.1.2 Competition Assays

Competitive binding assays involve incubating the receptor preparation with a mixture of ligands, one of which is radioactive (the reference radioligand, usually [^{3}H]TCDD in studies involving DLCs). The reference radioligand should bind more avidly than the unlabeled competitor(s)[66] and be present in sufficient concentration to saturate the receptor's binding sites. In the absence of any competitor, the maximum concentration of specifically bound receptor–ligand complex is formed; increasing the concentration of competitor, at a fixed concentration of the reference radioligand, reduces the level of bound radioactivity, ultimately to near zero. The usual objective is to determine the EC_{50}, the concentration of competitor that displaces 50% of the radioligand. At the EC_{50}, the radioligand and the competitor have equal occupancies of the AhR, and so their RBAs are in the ratio of their concentrations. Alternatively, binding ligands might be distinguished from nonbinding ligands by selecting a cut-off RBA as the limit of a positive response. For example, suppose that TCDD is the reference radioligand and that 10^{-5} is the cut-off RBA. For a concentration of radiolabeled TCDD of 1 nM (a reasonable value), a series of commercial chemicals to be tested could be prepared at 100 μM. The RBA will be $<10^{-5}$ if the bound radioactivity for radioligand + competitor is >50% of that for the radioligand alone. Relative EC_{50}s may reflect kinetic affinities or equilibrium affinities, depending on whether the association between receptor and ligands is freely reversible.[67]

The common graphical presentation of a competition assay is a sigmoidal curve of percent specific binding vs log (competitor concentration). The EC_{50} may be obtained either graphically (Figure 6) or, better, using a statistical technique such as the probit or logit method.[68] We have stressed elsewhere that the statistical uncertainty in the EC_{50} will be high unless a large number of competitor concentrations is used to define the sigmoidal curve.[69] Care must be used in interpreting the sigmoidal curve, because of the incorrect impression that at low ligand concentrations there is a threshold below which the level of specific binding (and by implication the toxic potency) of the DLC is insignificant [e.g. Roberts[70]]. This is an artifact of using a logarithmic concentration scale (Figure 7a and b).[71]

An advantage of the competitive method is that more than one unlabeled competitor can be present; an occupation ratio is established for the specific binding sites on the receptor, based on the relative concentrations and affinities of all the competitors. For a given competitor,

Figure 6 Example of a competition curve, demonstrating how an EC_{50} value is determined graphically.

Figure 7 The relationship between the receptor–ligand complex formed and the concentration of free ligand. When a logarithmic concentration scale is used (a), there is an apparent threshold below which the level of specific binding is insignificant. However, this is only an artifact of the logarithmic scale, as seen when a linear scale is used (b).

or mixture of competitors, the EC_{50} value is by definition equivalent to the concentration of the reference radioligand. In the case of the AhR, with 1.0 nM [^{3}H]TCDD as the reference radioligand, whatever the actual concentration of the competitor(s) at the EC_{50}, this will occupy the same fraction of the receptors as 1.0 nM TCDD. Therefore, a measure of the TEQ is obtained from a single experiment.

An important check on this methodology is to use the unlabeled form of the reference radioligand as the unlabeled competitor; the EC_{50} value for the unlabeled ligand should equal the concentration of the reference radioligand. In consequence, the EC_{50} concentration obtained from a competition experiment depends upon the concentration of the reference radioligand; therefore in comparing literature values of EC_{50}s one must take care to note the concentration of the reference radioligand. RBAs, however, are independent of the concentration of the reference radioligand.

In the analysis of an extract from an environmental matrix, the analyst prepares a series of dilutions of the initial extract and plots dilution (abscissa) vs bound radioactivity (ordinate). Aliquots of these solutions are incubated at a fixed temperature for a predetermined time with fixed concentrations of the AhR preparation and the reference radioligand. The bound radioactivity is conveniently expressed as the percentage of the maximum specific binding (%SB) obtained with the reference radioligand in the absence of competitor. The %SB is determined for each dilution, from which one can estimate the extent by which the initial extract must be diluted to produce 50% of the maximum specific binding. At this dilution of the environmental extract, the DLCs in the extract occupy half the receptor or other recognition sites (EC_{50}); the TEQ of the sample is then equal to the TEQ of the reference radioligand, from which one can work back to the concentration in the undiluted sample.

A complication for interpreting RBAs, whether they represent kinetic or equilibrium affinities, is that the receptor–ligand complex may be untransformed, partly transformed, or wholly transformed, depending on the conditions of the experiment and the source of the AhR.[51] This issue was not appreciated before transformation was recognized as a step in the mechanism of toxic action of TCDD. One clear-cut study is that of Bradfield et al.[37] using mouse hepatic AhR at 4 °C; their results refer to equilibrium, because mouse hepatic AhR neither inactivates[72] nor transforms[73] at a significant rate at this temperature, and so the Scatchard method of analysis is justified. In contrast, it is likely that most studies involving rat hepatic receptor near room temperature have been conducted under thermally inactivating, and hence kinetic, conditions.[67,69]

Competition assays all suffer from the disadvantage that the signal (in this case, the intensity of radioactivity) is maximum when there is zero competitor and declines asymptotically towards zero as the concentration of the competitor increases. The DL for the competition assay is therefore difficult to define. Schneider et al.[69] took a 20% reduction in specifically bound radioactivity to be distinguishable from the 100% level, which is equivalent saying that the TEQ of the unlabeled competitor must be at least 25% that of the reference radioligand. For 1 nM [^{3}H]TCDD, this corresponds to 0.25 nM TEQ. A typical experimental protocol employs 10-μL aliquots of competitor solution in a final 1 mL of incubation mixture, so the DL is 250 fmol TEQ per incubation mixture.

It is difficult to account for nonspecific binding quantitatively in a competition assay, unlike a saturation assay (see above). The usual approach is to determine nonspecific binding under conditions that no unlabeled competitor is present, and to assume constant nonspecific binding for the entire series of dilutions of the unlabeled competitor.

The competition assay was first applied to the analysis of environmental samples by Hutzinger et al.[74] Municipal fly ash was analyzed by incubating a fixed amount of [^{3}H]TCDD and a fixed amount of rat hepatic cytosol (containing AhR) with increasing amounts of an extract prepared from the fly ash at 0–5 °C. The amount of bound radioactivity was determined by sucrose density gradient centrifugation analysis (SDGC) (see Tsui and Okey;[75] Okey et al.[76]). This method involved treating the incubated mixture with dextran-coated charcoal to remove unbound and loosely bound radioligand, separating an aliquot by SDGC, collecting the fractions, and assaying each for its radioactivity, a very time-consuming procedure. The DL was in the range 100–200 pg of unlabeled TCDD. The authors recognized that the assay ''assesses the total biologic activity of the PCDDs/PCDFs in a sample and does not focus on only one specific congener'', and also that the DL of any such competition assay would be lower the higher is the specific activity of the radioligand. The method was later extended to a range of individual PCDDs and their brominated analogs,[77] and to the analysis of 3,3′,4,4′-tetrachloroazobenzene (TCAB) in a series of chloroaniline-based herbicides.[78] In these last two reports the receptor–ligand binding assay was compared with aryl hydrocarbon hydroxylase (AHH) induction; for PCDD, PCDF, and PCB analytes, the sensitivities of the two assays were similar, but with TCAB the receptor-binding assay was much more sensitive than AHH induction, probably because TCAB is more readily metabolized.

Bradfield and Poland[79] made several modifications to the receptor–ligand binding assay. Their approach differed from that of Hutzinger et al.[74] in the following

respects: (1) the reference radioligand was [^{125}I]-2-iodo-7,8-dibromodibenzo-*p*-dioxin, which can be obtained at much higher specific activity than [^{3}H]TCDD, permitting lower DLs to be achieved (3 pg of unlabeled TCDD); (2) they carried out the assay by removing excess ligands from the incubation mixture with dextran-coated charcoal followed by γ-counting, without using SDGC; (3) they used hepatic cytosol from the C57BL/6 mouse rather than the rat, having found that the mouse receptor is thermally more stable with respect to loss of binding ability;[37] and (4) they used a 16-h incubation at 4 °C. The assay was applied to a series of halogenated dibenzo-*p*-dioxins and dibenzofurans, with the recognition that other DLCs could in principle be analytes for the method. Besides its higher specific activity, 2-[^{125}I]-iodo-7,8-dibromodibenzo-*p*-dioxin is a good choice as the reference radioligand because it binds to the AhR almost as strongly as TCDD [cf. Goldstein and Barrett[66]]. Its disadvantage is its relatively short half-life of 60 days, which necessitates resynthesizing the ligand fairly frequently, compared with a tritiated ligand whose radiochemical half-life is 12.3 years.

The introduction of the hydroxyapatite (HAP) assay[80] greatly improved the convenience of the receptor–ligand binding technique. In this assay, proteins in the incubated mixture are adsorbed on HAP, excess loosely bound ligands are removed using buffer containing a mild detergent (Triton X-100), and the radioactivity is counted after suspending the protein–HAP pellet in scintillation fluid. Using [^{3}H]TCDD as the reference radioligand, the HAP version of the receptor–ligand assay was shown to be applicable to a range of substituted azobenzenes[81] and chlorinated stilbenes[82] in addition to PCDDs, PCDFs, and PCBs. Chlorinated stilbenes were unusual in that both AhR binding affinity and the induction of monooxygenase enzyme activity in rat H4IIE hepatoma cells showed no obvious dependence on ligand structure. The HAP assay is inapplicable, however, to AhRs that bind only weakly to DLCs, for example the human AhR, because the detergent washing step strips the DLCs from the receptor.[83]

Schneider et al.[69] carried out a detailed examination of parameters such as incubation time for a successful AhR ligand binding assay. Using [^{3}H]TCDD as the radioligand, C57BL/6 mouse cytosol as the source of AhR, and 23 °C as the incubation temperature, they showed that mixtures of ligands of widely varying structure behaved additively with respect to receptor binding activity, once their concentrations were expressed in terms of TCDD equivalents. In common with previous workers they found that RBAs varied in the order PCDDs > coplanar PCBs > nonplanar PCBs [but note that low RBA towards the AhR does not absolve nonplanar PCBs of suspicion of non-AhR-mediated toxic effects[84]]. It is important to add the cytosol preparation to the premixed ligands; if the ligands are added sequentially, the first ligand added occupies a disproportionate fraction of AhR binding sites.[67,69] This observation indicates that association between the ligand and the AhR is essentially irreversible at this temperature, signifying that most of the ligand–AhR complex had already undergone transformation by the time it was analyzed, so that RBAs determined under these conditions represent kinetic rather than equilibrium affinities for the AhR.

Hu et al.[17] compared the HAP AhR ligand binding assay and chemical analysis by GC/MS for the analysis of DLCs in environmental matrices, with emphasis on how the results were affected by the extent of sample cleanup. Matrices analyzed included fly ash, fish tissue, soil, pulp-mill sludge, and petrochemical catalyst wash water. Fish tissue and contaminated soil required extensive cleanup before meaningful assay results could be obtained. The bioassay was considered conservative in that the apparent TEQ detected was always as great as (and often much greater than) that found by GC/MS, even after including the contributions of coplanar PCBs. Further analysis by GC/MS identified much of the missing material as PAHs, which also bind to the AhR but which do not evoke dioxin-like toxicity. Although AhR binding assays can be used to screen unknown environmental samples for possible DLC contamination, they cannot provide quantitative information unless interfering analytes have been shown separately to be absent. In appropriate situations they would be useful for monitoring the progress of an environmental remediation program fairly rapidly and inexpensively, always remembering that AhR binding assays do not provide chemical identification of what actually binds the AhR and also that agonists and antagonist both give a positive response. In addition, the observed radiation intensity does not depend linearly upon sample TEQ. It approaches zero asymptotically when the TEQ of the sample greatly exceeds that of the radioligand, and so a series of serially diluted samples must be assayed in order to establish the numerical factor by which the original extract must be diluted in order to reach the EC_{50}.

Rao and Unger[85] suggested using the AhR affinities of different ligands to estimate risk of exposure to mixtures of congeners. Competitive affinities of the DLCs for rat AhR were used to estimate the fraction of each DLC congener in human adipose tissue that would be bound to AhR. Drawbacks to this approach include the need for congener-specific analysis, and assumptions about the equivalence of human and rodent AhR towards different DLCs, equivalence among DLCs with respect to bioavailability, and whether receptor occupancy is a sufficient criterion for toxicity. Among these factors, that

of equivalency of human and rodent AhRs is especially suspect, because they differ substantially in their thermal stability in vitro[72] and their affinity towards TCDD.[24,40]

2.2 Post-transformation Assays

This group of assays includes tests for the production of the transformed AhR–ligand complex and the production of nuclear AhR–ligand complexes, and downstream end-points such as monooxygenase enzyme induction and reporter gene assays in which the reporter gene product is under the control of a DRE. Transformation in vitro is temperature dependent; its rate varies with species (guinea pig > rat > human).[73,86] Transformation is accompanied by an increase in the strength of ligand binding[51] and can be monitored by following the loss of the ligand's ability to dissociate from the complex.[67] Other parameters that are altered by transformation are the change of molecular mass of the AhR resulting from the dissociation of protein subunits[87] and the properties of the dissociated subunits, such as the binding affinity of ALBS–ARNT to DNA[73,88] and the phosphorylating ability of c-src.[35] Transformation is difficult to follow because no simple methods yet exist to demonstrate the production of specifically the transformed or the untransformed TCDD–AhR complex, or to show that one of them has been produced to the exclusion of the other.

Petrulis and Bunce[89] studied the first step beyond ligand binding in experiments in which competing ligands were added sequentially to hepatic cytosol. At low temperature (0–4 °C), transformation is sufficiently slow in some species that the reversibly formed AhR–ligand complex can be distinguished from the transformed AhR in which the ligand is essentially irreversibly bound. Provided that binding occurs at all, even weakly binding ligands such as PCB 153 appear to induce transformation as effectively as TCDD. This was taken as evidence that the antagonism of TCDD-induced end-points by PCB 153 does not occur at the stage of dissociation of the multimeric AhR complex.

2.2.1 Gel Retardation Assay

The gel retardation assay can be used to show binding to a synthetic oligonucleotide containing the DRE consensus sequence. In this method, [^{32}P]adenosine triphosphate (ATP) is used to phosphorylate the oligonucleotide, which is then allowed to bind to a deficit of cytosolic AhR–ligand complex. The bound and unbound oligonucleotides are separated by nondenaturing polyacrylamide gel electrophoresis. Binding to the protein reduces the charge-to-mass ratio of the oligonucleotide, and it runs more slowly through the gel, hence the name gel retardation analysis. The retarded and unretarded bands

Figure 8 Autoradiogram of a gel shift assay experiment showing the AhR-bound [^{32}P]-DRE bands. Assay used guinea pig hepatic cytosol, treatments at 23 °C unless indicated. Lanes: 1, dimethyl sulfoxide (DMSO) (0 °C); 2, 10 nM TCDD (0 °C); 3, DMSO (30 °C); 4, 10 nM TCDD (30 °C); 5, empty; 6, DMSO; 7, 10 nM TCDD; 8, 100 μM PCB 153; 9, 100 μM PCB 153 + 10 nM TCDD; 10, 100 μM 3-methylcholanthrene (3-MC); 11, 100 μM 3-MC + 10 nM TCDD; 12, 1 nM TCDD; 13, 100 nM 3-MC + 1 nM TCDD; 14, 1 μM 3-MC + 1 nM TCDD; 15, 10 μM 3-MC + 1 nM TCDD.[90]

are visualized using autoradiography (Figure 8). A key advantage of this technique is that it does not require a radiolabeled ligand, as it is the oligonucleotide that is labeled. It can therefore be applied to any AhR-binding compound.

Safe's group studied the production of the nuclear complex by incubating radioligand with AhR and monitoring the accumulation of radioactivity in the nucleus.[91,92] The rates of transformation of the AhR–ligand complexes were parallel when two end-points were compared: translocation to the nucleus and formation of a shifted band in the gel retardation assay.[93] In principle, formation of the nuclear AhR–ligand complex could be used as an environmental assay, although a competition assay would be required to monitor an environmental sample because the latter is unlabeled. As with receptor binding, the experiment would consist of measuring the reduction in bound radioactivity when the environmental sample was incubated with a fixed aliquot of receptor and a fixed aliquot of radioligand.

Santostefano et al.[94] attempted to use the gel retardation assay to examine the relative potencies for AhR activation of different ligands. By the use of Woolf plots, they found that transformed complexes of the rat AhR with different ligands had similar affinities for oligo-DRE. Equilibrium binding between AhR–ligand complex and the oligo-DRE was demonstrated by showing that unlabeled DRE added later could displace the ^{32}P-labeled DRE from the AhR–ligand complexes. Ligands such as 1,2,7,8-tetrachlorodibenzofuran (TCDF), which binds weakly to rat AhR, produced less transformed AhR complex; this was proposed to be due to inactivation of the unliganded AhR competitively with binding. In principle, an assay for environmental samples could be developed

using a fixed amount of AhR, followed by incubation with a fixed amount of DRE to probe the environmental samples' ability to transform the AhR.

Petrulis and Bunce[61] studied the relative transforming ability of AhR ligands both singly and in combination, using cytosolic extracts from rat and guinea pig. Neglecting minor interspecies difference, ligands with high affinity for AhR [TCDD, 3-MC and 3,3′,4,4′-tetrachlorobiphenyl (PCB 77)] all produced comparable intensities of the shifted band upon gel electrophoresis. Weakly binding ligands such as PCB 153 and 2,3,3′,4,4′,5-hexachlorobiphenyl (PCB 156) gave only limited intensities of the shifted band. Combinations of productive ligands (those that exhibit high affinity for AhR and high toxic potency) at saturating concentrations yielded intensities similar to those resulting from a single high-affinity ligand; unproductive ligands at high concentration outcompeted lower concentrations of productive ligands. This behavior shows clearly that the mechanism of action of the unproductive ligands diverges at or before the DRE binding step in the mechanism, and that target molecule antagonism is a plausible explanation for the antagonism of the toxicity of productive ligands by unproductive ligands. At high total receptor occupancy, the ligands compete for a limited amount of the target molecule AhR, whereas at low total receptor occupancy, AhR sites are plentiful for occupancy by both ligands.

The biological relevance of the gel retardation assay may be limited because it employs an oligonucleotide which is only a short DNA fragment, precluding the possibility of reproducing multiple DRE occupancy which may be associated with toxicity in actual organisms. Although binding to native DREs occurs only after the AhR–ligand complex has dimerized with ARNT,[55] in vitro experiments with oligonucleotides are carried out without adding ARNT. It is not clear whether the in vitro system does not require ARNT or whether sufficient ARNT is present in broken-cell preparations of cytosol.

A current point of interest is whether antagonistic ligands that bind AhR fail to undergo transformation. Petrulis and Bunce[61] indicate that unproductive ligands such as PCB 153 induce dissociation of liganded AhR complexes as effectively as TCDD, but bind much less strongly to synthetic oligonucleotide. This phenomenon may also be species-dependent, since α-naphthoflavone–AhR complexes transformed much more efficiently (judged by gel retardation assays) when guinea pig was the source of cytosolic AhR compared with rat.[94,95] The possibility that mechanism-based bioassays may give species-dependent results led Denison et al.[96] to suggest that bioassays should be run in multiple species to assess toxic potency thoroughly, but that is impractical if the goal of bioassays is to achieve high throughput and low cost. The alternative might be to standardize the strain of animal or the cell line that is to be used in the assay, but at the risk of overlooking some of the DLCs present in environmental samples.

Other possible assays that could be devised include one based on detecting the formation of the ALBS–ARNT heterodimer, possibly using an Ab-based method. This would require an Ab that could recognize the ligand-bound ALBS–ARNT complex, rather than the individual components, and may not be practical. An assay could also be imagined in which the formation of the mRNAs following transcriptional activation was monitored, but this does not yet seem to have been attempted.

With respect to cancer as a toxic end-point, Büsser and Lutz[97] investigated an assay based on the ability of hepatocarcinogens, including TCDD, to stimulate unscheduled DNA synthesis. The protocol involved oral administration of the test substances to rats or mice, followed 24 h later by radiolabeled thymidine. Four hours later the animals were killed and the extent of radiothymidine incorporation into hepatic DNA was measured in comparison with untreated controls. The female rat and male mouse (but not male rat) showed increased DNA synthesis at TCDD exposure levels of 1–2 nmol kg^{-1}. The procedure is relatively fast, but a screening program would require large numbers of animals, in addition to which, no information is yet available about the responsiveness of other DLCs in the assay.

2.2.2 *Reporter Gene Assays*

Reporter genes are DNA sequences that encode for proteins or enzymes with characteristic activities that are unique to the cells used for the test and that are easily measured using conventional biochemical assays. As noted by Lewis et al.,[98] reporter genes were first employed for studying the mechanisms of transcriptional activation in cells, but have now become valuable tools in bioassay systems. Techniques are now available for transfecting new genetic material into the host cells so that the change is heritable over the long term (stable transfection), although the selection of the stable transfectants is very time consuming.[99] The alternative, transient transfection, does not provide indefinite stability, but allows more copies of the foreign DNA to be introduced into the host cell; transient transfection must always be used when the host cells are primary cultures, which are inherently viable only for short periods.

An early reporter gene to be developed was chloramphenicol acetyl transferase (CAT), an enzyme from *E. coli* that is foreign to eukaryotic cells. It is assayed by quantitating the acetylation products of the antibiotic chloramphenicol; the method carries an internal check

because only the cells that remain transfected survive in the presence of the antibiotic. The original CAT methods required the use of either radiolabeled chloramphenicol or radiolabeled acetyl coenzyme A in order to assay the enzyme product; more recently, fluorescent chloramphenicol derivatives have been developed to allow fluorescence as the assay method.[98] Many cell lines used for bioassays today are transfected with CAT or another antibiotic-resistance gene, in addition to the reporter gene whose gene product is the primary objective of the method. The antibiotic-resistance gene is present to monitor that the cells, which are grown in a medium supplemented with the antibiotic, retain their viability, and so that contaminant microorganisms will not survive.

In the context of analysis for DLCs, assay methods so far developed involve introducing DNA that encodes for an abnormal response into cells that already contain functional AhR machinery, usually immortal hepatoma cells. The foreign DNA is introduced downstream from the DRE; ligand binding followed by interaction with the DRE causes the translation of the reporter gene product in the bioengineered cells. Reporter gene assays require the DLC to undergo three stages in the mechanism of toxic action (ligand binding, transformation, and DRE binding) in order to observe a positive response; as such, they are not strictly receptor–ligand binding assays.

El-Fouly et al.[100] first reported linking AhR binding to the expression of an easily monitored gene product through the use of recombinant cell lines. They constructed, in AhR-containing mouse hepatoma cell lines, a stable recombinant vector that expressed human placental alkaline phosphatase (AP) under the control of a section of CYP 1A1 promoter that contains several DREs. Exposure to TCDD led to receptor binding, transformation, DRE binding, and dose-dependent expression of AP. The significance of the use of human placental AP is that this particular enzyme is unusually stable to heat. Other native phosphatases can be thermally denatured before monitoring the culture's phosphatase activity by measuring the rate of hydrolysis of *p*-nitrophenyl phosphate (a substrate for the enzyme) to *p*-nitrophenolate anion, which is easily monitored spectroscopically. In the presence of TCDD, AP activity was induced in a saturable, dose-dependent manner ($ED_{50} \approx 0.3$ nM). Other DLCs, including TCDF, 3-MC, PCB 77, and 3,3′,4,4′,5-pentachlorobiphenyl (PCB 126) (but not PCB 153) also induced near-saturating levels of AP activity. The rate of production of *p*-nitrophenolate was taken to be proportional to receptor occupancy by DLCs, although this implies the questionable assumption that all DLCs undergo stages subsequent to AhR binding with equal efficiency.

Several groups have recently introduced elegant variants of the AhR reporter gene assay in which AhR binding has been linked to activation of the LUC gene, which encodes for luciferase, the enzyme that is responsible for light emission in the common firefly. The significance of this technique is that the experimentally observed parameter is light intensity, which can be monitored easily and with high precision using a luminometer. Balaguer et al.[101] transiently transfected the luciferase reporter gene into Hepa 1c1c7 cells so that the luciferase gene was under the control of DREs. Ligand binding, followed by transformation and DRE binding, led to the translation of luciferase gene, leading to the dose-dependent emission of light when luciferin was added. This system was able to assay for TCDD itself, and for TCDD-like activity in black liquor from pulp and paper mills.

Murk et al.[102] obtained stable transfectants of the luciferase reporter gene in rat hepatoma H4IIE cells, and were able to analyze both reference compounds and PCB mixtures by means of this assay, which they termed chemically activated luciferase gene expression (CALUX). The reaction was carried out in 24-well plates, and with TCDD as a reference, the EC_{50} was reached at 10 pM. The DL, defined as three times the standard deviation of the DMSO blank, corresponded to only 0.5 fmol of TCDD per well. The maximum light emission, however, differed among analytes, presumably reflecting differences in the efficiency of events subsequent to AhR binding (transformation and/or nuclear translocation and/or DRE binding). The assay was applicable to both single DLCs and environmental samples, including sediment porewater[102] and blood plasma,[103] and it was suggested that the CALUX assay would provide a rapid and relatively noninvasive test for exposure to DLCs in wild-life. The same group has also developed a trout hepatoma cell line with the luciferase reporter gene; luminescence was measured by lysing the cells after 4 days of exposure to the DLC and adding standard luciferin reagents. TCDD had an EC_{50} for light emission of 0.06 nM (maximum intensity 100%, assumed); 1,2,3,7,8-pentachlorodibenzo-*p*-dioxin, 2,3,4,7,8-pentachlorodibenzofuran, PCB 126 and PCB 77 had EC_{50} (maximum intensity) 0.3 nM (120%), 0.2 nM (114%), 10 nM (110%), and 11 nM (43%), respectively. 2,3,3′,4,4′-pentachlorobiphenyl (PCB 105) and 2,3′,4,4′,5-pentachlorobiphenyl (PCB 118) were unresponsive in the assay.[104]

The CALUX system and the related P450 reporter gene system (P450RGS) have been commercialized by contract analytical laboratories. P450RGS utilizes human HepG2 hepatoma cells modified by the introduction of the luciferase gene. The P450RGS assay screens for a wide variety of planar aromatic xenobiotics,[92] prospectively allowing those environmental samples of the greatest potential concern to be identified for more detailed testing. PAHs are more responsive at short incubation times (6 h) and DLCs at longer times (16 h). The

relative light emission varied significantly among DLCs (TCDD, 27-fold induction; PCB 77, 15-fold; 2,3,4,4′,5-pentachlorobiphenyl (PCB 114), 19-fold; PCB 126, 111-fold; PCB 156, 6-fold; 3,3′,4,4′,5,5′-hexachlorobiphenyl (PCB 169), 29-fold), but it is not clear from the reported data whether these represent saturated responses. TEFs calculated from the P450RGS system were substantially different from the consensus values.[105] Although the P450RGS assay has been applied to the determination of the TEQ of environmental samples, it does not yet appear to have been established that mixtures of DLCs or PAHs respond additively in the assay. Consequently, TEQs obtained in the assay must so far be considered to be only semiquantitative.

The development of reporter gene assays is clearly more demanding than conventional ligand binding assays, but the potential payoff is a simpler assay protocol. The limitation of conventional saturation assays to radiolabeled ligands is overcome by using reporter gene assays, because the assay end-point is the phenomenon under the control of the reporter gene, such as light emission from luciferase. Reporter gene assays are always carried out as saturation assays, because all competitors for the same AhR binding sites act as potential agonists for the reporter gene. The data cited above[92,106] make it clear, however, that the intensity of light emission from different ligands is not necessarily equal even under conditions of saturation of AhR binding sites. This is consistent with unequal transforming or DRE binding ability of different DLCs. Experiments with 2,2′,5,5′-tetrachlorobiphenyl (PCB 52) in the recombinant assay involving firefly luciferase as the reporter gene product[107] indicate that the extent of DRE activation by less productive DLCs is also cell-line dependent.

2.2.3 Enzyme Induction Assays

Several assays have been developed in which the induction of a particular gene product has been monitored in vivo or in cell culture following exposure to TCDD. The most common end-point is the induction of a monooxygenase activity such as AHH or 7-ethoxyresorufin-*O*-deethylase (EROD). These are markers for the CYP 1A1 gene product (cytochrome P450 1A1), which is the principal form of cytochrome P450 induced by TCDD and PAHs such as 3-MC. CYP 1A2 is inducible by nonplanar PCB congeners[108] and also by TCDD;[109] its activity can be monitored by following the marker enzyme acetanilide-4-hydroxylase.[110] In addition, 7-pentoxyresorufin-*O*-deethylase (PROD) is a marker for the phenobarbital-inducible CYP 2B family of cytochrome P450s[111] and 7-ethoxycoumarin-*O*-deethylase (ECOD) is a marker for both phenobarbital- and TCDD-type inducers.[112] All of these enzyme assays have some degree of cross-reactivity among substrates; no substrate is known that has complete specificity for a single monooxygenase isozyme [reviewed by Hu and Bunce[113]]. Unlike the usual method of carrying out enzyme kinetics which employs constant enzyme and variable substrate concentrations, these assays employ a constant concentration of substrate that is optimized so that the reaction rate $V \approx V_{max}$. Under these conditions the rate of product formation is proportional to the enzyme concentration.

The usual protocols for the AHH induction assay[114] involve incubating a preparation of lysed induced cells (and uninduced controls) with a standard solution of benzo[*a*]pyrene and reduced nicotinamide adenine dinucleotide (NADPH) in the presence of oxygen. The reaction involves the hydroxylation of benzo[*a*]pyrene, one of whose products, 3-hydroxybenzo[*a*]pyrene, is monitored by its characteristic fluorescence at 522 nm.[115,116] AHH activity is reported as picomoles of 3-hydroxybenzo[*a*]-pyrene equivalents formed per unit time per milligram of total protein. Studies of AHH activity frequently employ the rat hepatoma cell line H4IIE, which has low basal activity, but whose activity is readily induced by 3-MC[117] and TCDD.[118] The protocol was refined by Sawyer and Safe[119] as a rapid screening tool for the detection of planar halogenated aromatic compounds. The EROD assay is carried out in a similar fashion,[120] in which the lysed cells are incubated with NADPH and 7-ethoxyresorufin, and the reaction is followed by monitoring the fluorescence of the product resorufin at 582 nm. The assay results are reported as picomoles of resorufin formed per unit time per milligram of total protein. The EROD assay is greatly preferred over AHH, because it avoids the use of the highly carcinogenic benzo[*a*]pyrene.

A key advantage of the AHH and EROD assays is that the parameter detected is fluorescent light intensity, which allows the possibility of low DLs, automation and easy data handling. The protocol for the analysis of unknowns involves preparing a calibration curve of fluorescence intensity vs TCDD concentration and reading the TCDD equivalent of the unknown directly from the curve. The introduction of fluorescence plate readers has permitted the EROD assay to be carried out in 48- or 96-well plates.[121]

Both AHH and EROD assays can be carried out using animal tissue or, more commonly, with cells in culture. When whole animals are used, the CYP 1A activity of microsomal preparations of the livers of killed animals is compared with that of hepatic microsomes from control (unexposed) animals. Examples include the work of Parrott et al.[122] on the accumulation of PCDDs in rainbow trout and of Diliberto et al.[123] on tissue distributions of TCDD in mice. Machala et al.[124] used chick hepatocytes for EROD analysis, with injection of

test substances on day 14 of incubation and killing and removal of the livers 24 h later. The assay was applied to eggs treated with individual DLCs but not to mixtures or environmental samples.

The rat hepatoma cell line H4IIE has been extensively used as a convenient standard procedure for assaying environmental samples using cell cultures. Many other hepatoma lines, from humans, rodents, and fish, have also been developed. Primary cultures of hepatocytes are also used for EROD analysis [e.g. Kennedy et al.;[121] Bosveld et al.;[125] Dubois et al.[126]]. Primary hepatocytes are readily prepared, allow the examination of any species of interest, and, it has been argued, are more representative of the metabolism of the normal animal than immortal cell lines.

Because enzyme assay activities are reported in units such as femtomoles per minute per milligram of protein, the total protein content of the biological preparation must be measured. This is usually done using either the method of Lowry et al.[127] or Bradford;[128] more recently, Lorenzen and Kennedy[129] introduced a method based on fluorescamine association that can be carried out by fluorescence assay in the same 96-well plates that are used for EROD analysis.

TEQ values are estimated from enzyme induction experiments by preparing a calibration curve of enzyme activity vs dose of TCDD incubated with the cells. The ability of the environmental sample to induce AHH or EROD is then compared with the dose of TCDD needed to induce the enzyme to the same extent. With respect to DL, the EROD assay is able to detect low concentrations (typically $<10\,\text{pmol}\,\text{L}^{-1}$), because fluorescence is the experimentally observed parameter.

Monooxygenase enzyme induction is regarded as a normal, adaptive metabolic response to exposure to AhR-binding xenobiotics rather than a toxic response[130,131] [although recent work suggests that the induction of CYP 1A1 by TCDD causes oxidative damage to DNA[132]]. The justification for using enzyme assays to estimate TEQs is the well-established rank-order correlation among DLCs between the doses required for enzyme induction in cell culture and in vivo effects such as thymic atrophy and body weight loss in whole animals.[47,133] In common with overtly toxic end-points, enzyme induction requires the toxicant to initiate all of the biochemical steps from receptor binding through to DRE binding and mRNA transcription. Clemons et al.[134] have shown a good correlation in wild fish between TEQs determined by GC/MS and those obtained by EROD assay using either H4IIE cells or a rainbow trout cell line designated RTL-W1. This represents an important validation of the enzyme induction assay with real samples (see Figure 9a and b).

Considerable effort has recently been invested in comparing different monooxygenase enzyme assays because

Figure 9 EROD induction by four nonortho coplanar PCBs (PCB 77, PCB 81, PCB 126, and PCB 169) and three mono-ortho coplanar PCBs (PCB 105, PCB 118, and PCB 156) in (a) H4IIE and (b) RTL-W1 ($n \geq 3$). [Reproduced by permission from J.H. Clemons, L.E.J. Lee, C.R. Myers, D.G. Dixon, N.C. Bols, 'Bioassays for the Analysis of Dioxin-like Compounds', *Can. J. Fish. Aquat. Sci.*, **53**, 1177–1185 (1996).[134]]

of their important application of screening industrial effluents, particularly in the context of the toxicity of pulp-mill effluents towards fish in their receiving waters.[135–137] This effort followed the observation in the 1980s that chlorine-bleaching mills emitted small quantities of PCDDs and PCDFs. The toxicity and monooxygenase enzyme activity of pulp-mill effluents did not correlate with DLC concentration: both responses were also observed downstream of mills that used no chlorine. These observations reinforce the point that monooxygenase enzyme activity can be induced by many AhR-binding compounds, not all of which are DLCs, and not all of which are necessarily toxic.

Sanderson et al.[138] compared the DL obtained from EROD analysis using H4IIE cells with the value obtained based on light emission from H4IIE cells that had been genetically modified to contain the luciferase reporter gene. The latter technique gave a threefold lower DL on exposure to TCDD (0.8 pmol L^{-1}). Hodson et al.[137] compared the work of several groups with regard to DLs and ranges of quantitation in monooxygenase assays. Most of the studies reviewed report the induced EROD activity vs log[TCDD], and so "ranges of linear response" actually refer to the almost linear central portion of the sigmoidal dose–response curves [see Figure 7a]. This accounts for the similarity between the reported EC_{50} values and the DLs of the assay. For the commonly used rat hepatoma H4IIE cell line, typical results are a log-linear range about 10–200 pM TCDD, with an EC_{50} of ~20 pM TCDD and a DL of ~10 pM TCDD.[138] Primary chicken embryo hepatocytes show a log-linear range of about 1–100 pM TCDD, $EC_{50} \approx 20$ pM TCDD, and DLs of ~1 pM TCDD.[124] In the rainbow trout liver cell line RTL-W1, a log-linear range of about 2–20 pM TCDD, $EC_{50} \approx 15$ pM TCDD, and DLs of 2 pM TCDD were reported.[134] Luciferase expression in reporter-gene assays in HepaG2 and Hepa1c1c7 cells typically demonstrated a wider log-linear range of about 10–1000 pM, but the EC_{50} values and DLs were increased to approximately 100 pM TCDD and 50 pM TCDD, respectively.

Parenthetically, Hodson et al.[137] also reviewed the use of passive devices based on semipermeable membranes for preconcentrating natural and effluent water samples in order to increase the concentration of DLCs prior to EROD analysis. By the choice of triolein inside the membrane, the deployment device is able to mimic, to some extent, the behavior of an aquatic organism in bioconcentrating these xenobiotics from water.

A limitation to the use of monooxygenase enzyme assays is that their activity may be species-dependent. Dubois et al.[126] observed different patterns of dose vs EROD activity in quail hepatocytes, rat hepatocytes, and the human hepatoma line HepG2 when comparing enzyme induction by PCB 77 and the commercial PCB mixture Aroclor 1254. In experiments with rats, DeVito et al.[110] found that the relative EROD induction potencies of different DLCs varied with the tissue tested, and they cautioned against the universal applicability of hepatic EROD induction potencies.

The curves of fluorescence intensity vs concentration for different inducers are displaced along the abscissa (Figure 9a and b), as would be expected for compounds with different TEFs, and so the abscissa of the curve for a mixture represents TEQ. EROD activity is a saturable response, because beyond a certain concentration of DLC all AhR sites have been occupied and CYP 1A1 production has been maximized. There are, however, two consistent findings that complicate the interpretation of data obtained from EROD assays: (1) different DLCs yield dissimilar values of the maximum (saturable) fluorescence intensity; and (2) for many DLCs, EROD activity declines when the concentration of the inducer exceeds the saturating value (Figure 10). This phenomenon has been the subject of some controversy.[139] Recently it has been shown that DLCs not only induce CYP 1A1, but also act as competitive inhibitors of the deethylation of the enzyme substrate, 7-ethoxyresorufin.[61,140] This leads to biphasic curves when cells in culture are treated with increasing amounts of the DLC: the EROD activity increases at low [DLC], as more enzyme is induced, but falls again once the induction response (which is AhR

Figure 10 EROD activity in primary rat hepatocytes incubated for 24 h with TCDD, 3-MC, PCB 77, or PCB 153. Activities are relative to the activity obtained following treatment with 1 nM TCDD. Error bars represent the standard deviation of the calculated EROD activities.[89] (Redrawn from J. Petrulis, PhD Thesis, University of Guelph, 1998.)

mediated) has become saturated, because additional DLC inhibits the enzyme. The quantitative EROD response becomes further complicated when mixtures of inducing agents are present or when the inducer is metabolized concurrently with enzyme induction.[61] This has also been implied by experiments in which the length of exposure of cells to the inducing agents is varied: the apparent EC_{50}s of some DLCs increased at longer exposure times, on account of differential rates of metabolism.[141] Furthermore, Aarts et al.[95] disclosed that the extent of antagonism between TCDD and either PCB 77 or 2,2′,3,3′,4,4′-hexachlorobiphenyl (PCB 128) was species and cell-line dependent in luciferase reporter gene assays. For all these reasons, caution must be employed when using EROD and related enzyme assays in the mode of inducing enzyme activity by incubating cells with an environmental extract.

Competitive inhibition does not apply to the use of monooxygenase assays for assaying the enzyme activity of hepatic microsomes, when detecting prior exposure of wild-life to DLCs. In that application, there is no carryover of the DLCs into the microsomal preparation, and so competitive inhibition of the enzyme does not occur.

Another potential problem is the antagonism, or masking, of the effects of one DLC by another. This has been observed in the EROD assay by Hasspieler et al.,[142] who tested coplanar PCBs together with TCDD as inducers of EROD activity in the human hepatoma cell line HepG2. PCB 77 and PCB 169 had similar behavior: neither induced EROD activity alone, but each inhibited EROD induction by TCDD. PCB 126 was a weak EROD inducer on its own; it weakly antagonized induction by a high dose of TCDD, but had little effect at lower doses of TCDD. Similarly, Janz and Metcalfe[143] found less than additive induction of AHH in intact rainbow trout treated with TCDD and PCB 77. In a 13-week, low-dose feeding study in rats, Van Birgelen et al.[144] found evidence for nonadditive behavior between TCDD and PCB 156 in several end-points. These observations are consistent with target molecule antagonism, when high concentrations of DLCs compete for a limited stock of AhR,[67] or with competitive enzyme inhibition. The combination of target molecule antagonism and competitive enzyme inhibition makes it clear that enzyme activity assays for CYP 1A1 may underestimate the TEQ of a complex environmental mixture.

Both the foregoing effects come into play in the interpretation of the study by Bosveld et al.,[125] who studied the effects of the interaction between TCDD and the nonplanar PCB 153 on EROD activity in chicken embryo hepatocytes. The ratio [TCDD] : [PCB] was kept constant at $1 : 10^4$ for every dose of the toxicants, reflecting their typical ratio in environmental samples. EROD activity was found to peak at [TCDD] $\approx$ 1 nM, followed by a fall in activity as the TCDD concentration was increased further. Viability assays on the hepatocytes demonstrated that the decrease in activity was not due to cytotoxicity at the high doses of TCDD.

2.3 Markers of Abnormal Metabolism

A well-studied end-point following DLC exposure is the hyperaccumulation of hepatic uroporphyrin III (UP-III). As in all cases of abnormal metabolism, the question arises as to whether the end-point observed can be more than a marker of exposure, i.e. does it really parallel toxicity?

The overproduction of UP-III in the liver, and the related human disease porphyria cutanea tarda, are observed in animals following exposure to many halogenated aromatic compounds. The link to an AhR-mediated pathway was established by showing that inhibitors of cytochrome P450 1A1 suppressed the overproduction of UP-III [reviewed by Bonkovsky et al.[145]] and that UP-III accumulation paralleled AHH activity in AhR-responsive and -nonresponsive mice.[146]

Later work revealed that the link between porphyrin metabolism and the induction of cytochrome P450 enzymes is an indirect one. UP-III is principally formed from uroporphyrinogen III by the action of cytochrome P450 1A2; when cytochrome P450 1A2 is induced [e.g. by nonplanar PCBs such as PCB 153[147]], uroporphyrinogen III is diverted from its normal route in heme biosynthesis. Knockout mice lacking CYP 1A2 activity had less uroporphyrinogen oxidation activity than wild-type mice;[148] in human hepatoma cells, CYP 1A1 and CYP 3A4 also contributed to uroporphyrinogen oxidation activity.[148] Normally, heme suppresses the formation of uroporphyrinogen III through feedback inhibition, thus the

Figure 11 The pathway of porphyrin metabolism, showing the proposed mechanism of hepatic porphyrin accumulation. (Redrawn from A.P.J.M. van Birgelen, J. Van der Kolk, K.M. Fase, I. Bol, H. Poiger, M. Van den Berg, A. Brouwer, *Toxicol. Appl. Pharmacol.*, **126**, 202–213 (1994)[144].)

diversion of uroporphyrinogen III causes a build-up of UP-III (Figure 11).

Studies on rats dosed with mixtures of TCDD and PCB 153 showed that the effect of the two compounds was highly synergistic. Neither TCDD alone nor PCB 153 alone promoted significant accumulation of UP-III, which most likely involves the induction of both CYP 1A1 and 1A2. In addition to monooxygenase induction,[146] TCDD induces δ-aminolevulinic acid synthetase,[150] which is required for the further synthesis of uroporphyrinogen III.[151] The 1A2 isozyme is induced by the nonplanar PCB, thereby promoting the oxidation of uroporphyrinogen III to UP-III. Although porphyrin accumulation can be regarded as an AhR-mediated process, the interactive effects among DLCs are clearly complex, and not completely understood.

The accumulation of hepatic porphyrin in chicken embryos[151,152] has been suggested as a useful marker for the exposure of avian species to DLCs. Individual DLC congeners had broadly similar relative potencies with respect to EROD induction and porphyrin accumulation in primary hepatocytes from chicken and pheasant.[153] Interactive effects between TCDD and several PCB congeners have been studied in primary chicken hepatocytes.[154] For both planar and nonplanar PCBs it appeared that significant porphyrin accumulation only occurred at doses higher than those at which EROD induction was maximum (where the occupancy of the AhR is also maximum). One of the combinations examined by Tysklind et al.[154] was TCDD + PCB 153. At a fixed concentration of TCDD that caused maximum EROD induction but no porphyrin accumulation, increasing levels of the PCB depressed EROD activity and led to porphyrin build-up. We can explain the depression of EROD activity (primarily CYP 1A1) in terms of target molecule antagonism (PCB outcompeting TCDD from AhR binding sites) and competitive enzyme inhibition; this must occur at a PCB concentration that does not induce maximum CYP 1A2. These interactive effects among DLCs make it difficult to calibrate porphyrin accumulation as a quantitative assay for evaluating the toxic potency of environmental samples. Complicating the matter further is the observation that the extent of porphyrin production in the liver following exposure to PCBs is apparently related to the concentration of iron in the liver,[155] an additional parameter that would need to be addressed in the development of a quantitative assay.

3 IMMUNOASSAYS

Immunoassays depend upon the recognition of an antigen (or foreign molecule) by an Ab, which is a soluble protein that has been produced by B-lymphocytes in a live animal. Exposure to a particular antigen causes the proliferation of the B-cell clone that produces the antigen-specific Ab, such that an immune response can be mounted in response to a subsequent exposure to the antigen. Immunoassays are based on exploiting the high affinity of an Ab for the antigen to which it was raised. The actual assay requires both the recognition and quantitation of free analyte in a test solution; the latter is usually accomplished using a competition assay, although a wide variety of assay methods has been described [reviewed by Sherry[156]].

Immunoassays can be used to detect and quantify large biomolecules such as specific proteins or parts of proteins, polysaccharides, or nucleic acids at low concentrations, e.g. <10 fmol of the N-terminal region of the AhR itself.[157] They have become standard methods of analysis in clinical laboratories, where they have been adapted for use in the rapid, automated analysis of large numbers of samples.

Antibodies are normally produced in response to molecules having molecular mass >1000. Small molecules such as TCDD therefore do not elicit an immune response on their own, and so the antibodies must be raised by covalently binding the small molecule (termed a hapten) to a carrier protein that can produce a response and then injecting the conjugate into a live animal. For TCDD analysis, an extensively used hapten is 1-(*N*-adipylamino)-3,7,8-trichlorodibenzo-*p*-dioxin, which is a TCDD molecule one of whose chlorine substituents is replaced by a linking moiety that connects it covalently to the carrier protein (Figure 12).[158,159] If such a protein–hapten conjugate is injected into a live animal, some of the antibodies produced may subsequently be able to recognize the hapten–protein conjugate while others may recognize only the unattached hapten.

Antibodies produced as just described are termed polyclonal antibodies: they are produced by multiple clones of cells, each of which contributes one type of Ab. The antibodies bind to the antigen by way of many different specific recognition elements or epitopes that are functions of the size, shape, and hydrophobicity of different regions of the protein–hapten conjugate. Most of the polyclonal antibodies will interact with epitopes on the carrier protein itself, rather than recognizing the hapten. Even if the hapten is part of the recognition site,

Figure 12 Structure of the protein conjugate of 1-(*N*-adipylamino)-3,7,8-trichlorodibenzo-*p*-dioxin.

it is unlikely that an Ab will recognize the hapten alone, rather than the hapten plus part of the carrier, unless the hapten has a molecular mass above 1000.

Polyclonal Ab assays for DLCs were reported around 1980 [for TCDD, Albro et al.;[159] for TCDF, Luster et al.[160]]. In these assays the DLC molecule was bound covalently to the carrier protein by an *N*-adipylamido chain, and the antibodies were produced in rabbit. The assay was carried out by a radioimmunological method in which the unlabeled DLC and the appropriate *N*-adipylaminotrichlorodibenzofuran or -dibenzo-*p*-dioxin, labeled with ^{125}I in the adipyl chain, competed for the Ab. The complexed antibodies were precipitated with goat anti-rabbit γ-globulin and γ-counted for ^{125}I. The greater the concentration of unlabeled DLC, or in the case of cross-reactivity experiments the higher its affinity for the Ab, the less radioactivity was detected in the pellet. For pure TCDD, as little as 0.08 pmol could be detected by this method. Competitive radioimmunoassays suffer from the same disadvantages as competitive ligand binding assays: it is the labeled competitor rather than the analyte that is actually detected, and the response is saturable, with the signal (bound radioactivity) declining to zero as the concentration of the analyte increases.

A general problem with polyclonal antibodies is poor recognition of the hapten and interference by those antibodies that recognize different structural motifs. In addition, the particular range of antibodies formed varies with time in a given preparation, and from animal to animal among different preparations, making it impossible to standardize methods between different laboratories. These limitations can be avoided by the use of a monoclonal Ab, which is a unique protein derived from a single cloned cell line, and which can recognize the analyte specifically. Rather than attempt to separate a single protein from the polyclonal Ab mixture, a more successful approach is to separate the individual cells that produce the specific monoclonal Ab. This is done by fusing cells from an immortal cell line to spleen cells that have been previously exposed to the protein-linked hapten. The resulting hybridomas are then screened to select a particular cell that secretes an Ab that recognizes the hapten. With luck, a hybridoma can be selected with the ability to form antibodies that recognize specifically the free ligand; this cell line can then be grown up indefinitely in culture.

The monoclonal Ab is uniform and can be distributed to different laboratories, allowing the development of standardized assay procedures. Among the advantages of an optimally selected monoclonal Ab are ease of use, minimal sample preparation, low cost per sample, reproducibility, high selectivity for the analyte, small sample size, and potential for both automation and use in the field.[155,156,161] Disadvantages include the long development time and high cost of obtaining the monoclonal Ab, including hapten synthesis and screening thousands of hybridomas, and problems of cross-reactivity from related and unrelated analytes. The latter problem means that independent (chemical) confirmation of the analyte responsible for the response is necessary. In addition, a single immunoassay cannot respond to analytes of different structural types as can a chemical assay such as GC/MS.

In the case of TCDD analysis, monoclonal antibodies were first developed by Kennel et al.[162] and Stanker et al.[158] Kennel et al.[162] used the same assay approach as Albro et al.,[159] namely radioimmunoassay in which the DLC competes with a ^{125}I-labeled reference ligand. The hybridomas were obtained by the fusion of murine spleen cells with murine myeloma cells, and the hybridomas were screened for their ability to recognize TCDD by identifying those that could bind to bovine serum albumin that was covalently coupled to trichlorodibenzo-*p*-dioxin. As stated by Gilman et al.,[163] ''(The) ideal patterns for PCDD analysis are either high selectivity for only one specific PCDD congener or a pattern of crossreactivity for a wide range of PCDD-like compounds that mimics (their) relative toxicity''. These authors reported the development of immunoassays based on haptens that are structurally closer to TCDD than the original adipylaminotrichlorodibenzo-*p*-dioxin used by Stanker et al.,[158] in an attempt to improve specificity. In recent work, this group reported haptens based on 2-alkenyl-3,7,8-trichloro- (or -7,8-dichloro)-dibenzo-*p*-dioxin that have a working range of 2–240 pg per well for the TCDD surrogate 2-methyl-3,7,8-trichlorodibenzo-*p*-dioxin.[164]

Stanker et al.[158] developed an ELISA for PCDDs. In an ELISA, an enzyme is covalently linked to the monoclonal Ab, and the final assay method involves detection of the product of the enzyme–substrate reaction by some convenient chemical or physical method of analysis. A standard aliquot of the hapten or a simple hapten derivative is initially adsorbed to a plastic surface, such as those on a 96-well plate. The Ab and the solution to be analyzed are placed into the well, where the Ab complexes competitively to the plastic-bound hapten and the free analyte in solution. After equilibration, the solution phase is removed. The plastic-bound Ab complex is quantitated by adding the substrate for the Ab-linked enzyme; the enzyme product is detected by a standard method such as fluorescence or colorimetry, and so the concentration of enzyme product is a measure of the adsorbed Ab–hapten complex. In this type of competition assay the maximum signal is obtained when the solution being tested contains zero hapten; the greater the concentration of hapten in the test solution, the smaller is the concentration of enzyme product detected.

An alternative protocol involves immobilizing the Ab on plastic in 96-well plates. This is incubated with the test DLC mixture and a fixed aliquot of a competitor–enzyme conjugate. After removing the solution phase, the enzyme substrate is added and the amount of enzyme product is determined by how much competitor–enzyme conjugate is bound to the Ab (again, the less DLC in the sample, the more enzyme product is formed). DLs in the range of 0.1 ng of TCDD have been reported,[165] using a mouse monoclonal Ab having specificity for tetra- and pentachlorinated dibenzo-*p*-dioxins that roughly parallels their I-TEFs. A similar approach was used to prepare monoclonal antibodies that recognized coplanar PCBs in the presence of larger amounts of the nonplanar congeners,[166,167] using as the hapten a 4-alkoxy-3,3′,4′-trichlorobiphenyl linked to the protein through a terminal carboxyl on the 4-alkoxy substituent. However, various ''PCB fragments'' (i.e. substituted dichlorobenzenes) were more reactive with the Ab than PCB 77 which severely limited the usefulness of this approach. A recently reported electrochemical immunosensor is claimed to overcome this problem;[168] the Ab is immobilized on an electrode surface by entrapment in an electrically conducting polypyrrole matrix. The signal in this case was the current produced in response to a pulsed voltage waveform on the sensing electrode. Linear calibration curves for Aroclor mixtures were obtained up to (at least) $100\,ng\,L^{-1}$, and DLs of $0.4–3\,ng\,L^{-1}$, depending on the Aroclor mixture, with low cross-reactivity with non-PCB chlorinated compounds.

In principle, monoclonal antibodies could be developed as probes to recognize individual DLCs, by screening appropriate hybridomas. In practice, this has not been very successful because of problems of cross-reactivity.[158] The recognition sites on monoclonal antibodies are fairly large (~2–3 nM in diameter) compared with the size of the analyte of interest (0.3×1.0 nM in the case of TCDD), and so other molecules of similar size and hydrophobicity can be accommodated almost equally well.[169] This makes the monoclonal Ab assay more applicable to DLCs as a class than to the quantitation of individual DLC congeners. A calibration curve can be constructed using test solutions containing known concentrations of TCDD, in which case the assay measures the total concentration of DLCs as TCDD equivalents.

An ongoing criticism of Ab methods for assaying DLCs is their higher DLs compared with GC/MS. The group at Cape Technologies has successfully validated their enzyme immunoassay down to the picograms per gram level for both fly ash[170] and soil[171] samples, with excellent linearity between enzyme immunoassay and GC/MS methodologies. Sugawara et al.[172] have recently introduced a polyclonal ELISA for TCDD with a DL of <1 pg per well, based on horseradish peroxidase activity as the enzymatic detection system. Hapten–protein conjugates were based on 2,3-dichloro-7-(3′-propenoic acid) derivatives. A point of interest was the use of 2-methyl-3,7,8-trichlorodibenzodioxin as a less toxic surrogate for TCDD; the two compounds behaved almost identically in the assay.

To a limited extent, an assay for DLCs based on monoclonal antibodies resembles the competitive AhR ligand binding assay (section 2.1.2). In each case a protein is used to complex the DLC, and a reference ligand (in this case the immobilized hapten) and the DLCs in the test solution compete for a limited amount of protein. Because the monoclonal Ab recognizes the ligand, its binding site is a model for the binding site of the AhR: how accurate a model depends on the similarities between the binding sites, which is a matter of chance. Cross-reactivity between DLCs is observed because each DLC in the sample binds to the Ab according to its relative affinity and its concentration. Therefore, the TEQs obtained by immunoassay may differ from those from the receptor binding assay, because of different relative affinities of DLCs for the two proteins. The immunoassay is not mechanism based because the DLCs do not interact with the Ab as part of the biological mechanism of action.

Like the AhR binding assay, immunoassays tend to be conservative in recognizing more analytes than are toxicologically relevant. This has already been noted in the case of recognition of ''PCB fragments'',[166] and was also observed by Stanker et al.[158] and Vanderlaan et al.,[169] who compared immunoassays of several environmental matrices to analyses by GC/MS. Immunoassays consistently showed more of the ''toxic'' PCDDs and PCDFs than GC/MS, and in some cases the discrepancy was substantial.

Another aspect of DLC toxicology that has been exploited as a bioassay is immunosuppression. Spleen cells from a test species are combined with sheep red blood cells (SRBCs) and DLCs. After 5 days, the spleen cells are resuspended and plaqued. The number of plaques in the red blood cell lawn are counted and reported relative to the number of viable cells. DLCs have been demonstrated to cause a concentration-dependent suppression of the splenic plaque-forming cell (SPFC) response to SRBCs.[173] The utility of this technique as a screening assay is questionable as recent studies have shown that the response to mixtures of DLCs is not additive. The assay is very sensitive to TCDD, causing significant suppression at doses as low as $1\,\mu g\,kg^{-1}$, but PCB 153 has actually been found to enhance the response.[174]

4 EARLY LIFE STAGE BIOASSAYS

Interest in this research area has recently been high because of the recognition that the AhR may be necessary for proper development in a wide range of tissues.[175] In addition, AhR binding substances may alter the actions of endogenous hormones indirectly; for example, exposure to TCDD increases the rate of metabolism of estradiol, presumably by upregulating CYP 1A enzymes.[176] In utero exposure to DLCs causes clear reproductive abnormalities in rodents, and there is limited evidence for such effects also in humans.[177] Willey et al.[178] have shown that the AhR is transcriptionally activated during development in tissues known to be adversely affected by exposure to DLCs. To date, no endogenous ligand for activating AhR during development has been identified.[175]

TCDD shows dose-dependent AhR-mediated teratogenicity in mice, with the most prominent effect being cleft palate.[179–182] The dams are exposed to TCDD around days 7–10 of gestation and killed on day 18 for examination of the fetuses. Besides being inconveniently time consuming and requiring large numbers of animals, this end-point shows marked interactive effects between PCBs and TCDD. Certain nonplanar PCB congeners are able to antagonize TCDD-induced teratogenicity when administered at doses in the range of 10^4 times the teratogenic dose of TCDD, while planar PCB congeners are themselves teratogenic.[179,181,183] The rationalization of these observations is that PCBs and TCDD compete for a finite quantity of AhR. The complexes formed between the AhR and TCDD, and between the AhR and the toxic PCBs go on to cause the teratogenic response, whereas the complexes formed with the protective PCBs do not. When the total receptor occupancy is high, a nontoxic or antagonistic substance can protect against the effects of a toxic substance by binding unproductively to the AhR, thus in a sense displacing the toxic ligand.[67] This effect is not seen at low total receptor occupancy when there are sufficient receptor molecules available to bind all ligands.

Recent interest in environmental estrogens, and the more general phenomenon of endocrine disruption,[184] have focused attention on the role of TCDD (and potentially other DLCs) in developmental and reproductive toxicology. Although the mechanisms of action are not yet clear, it is already apparent that TCDD has strong interactive effects with steroid hormones (although there is no cross-reactivity between TCDD and steroid hormone receptors). In one recent paper, TCDD was shown to block the binding of the estradiol–estrogen receptor complex to estrogen response elements on DNA, while conversely estradiol blocked the association of the TCDD–AhR complex to DREs.[185] TCDD and other DLCs, notably 6-methyl-3,7,8-trichlorodibenzofuran, inhibit the growth of the MCF-7 human breast cancer line.[186,187] TCDD is also developmentally toxic to laboratory rats, causing demasculinization of male pups when administered at sublethal doses to the dams during gestation.[188] These effects, which persist into maturity, may be due to TCDD-induced elevation of the levels of mixed-function oxidase (MFO), thereby enhancing the metabolism of steroid hormones, but this has not yet been demonstrated experimentally. These recent observations have led to interest in developing assays to test for adverse effects of DLCs in early stages of life.

The interest in developmental toxicity is not really new, because some of the earliest concerns of TCDD exposure were "toxic fat syndrome" in young chickens in the 1960s, and the debate in the 1970s over whether forest spraying programs could cause human birth defects and miscarriages. Both of these situations involved the use of the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), which contained parts per million levels of TCDD as a contaminant introduced during manufacture.[189]

In the case of toxic fat syndrome, a characteristic finding was the development of pericardial edema in newborn chicks, whose early death caused substantial economic loss in the broiler chicken industry. Higginbotham et al.[190] suggested this as a bioassay end-point. In related work, Flick et al.[191] showed a dose-dependent reduction in hatchability when eggs were treated with TCDD. Rifkind et al.[152] correlated histopathological changes including hepatic edema in chick embryos with the induction of AHH and EROD activity, and Brunström[192] correlated hatchability with EROD induction, in each case after dosing eggs with various PCB congeners.

Helder[193,194] demonstrated the toxicity of TCDD towards fish and their embryos, and developed an assay based on the lethality of DLCs towards yolk sac fry of *Salmo gairdneri*.[195] Similar assays have been introduced for rainbow trout, fathead minnow, and Japanese medaka. In more recent studies, the toxicants have been injected into the developing fish, rather than exposure through the water, to control the dose more precisely [for the technique, see Metcalfe et al.;[196] Walker et al.[197]]. Zabel et al.[198] found that pairs of PCDD and PCB congeners behaved nearly additively (no deviations greater than 2–3-fold) in an early life stage assay in rainbow trout. The same group assessed a complex PCDD–PCDF–PCB mixture in lake trout as having close to the additive lethality of its components.[199] LD_{50}s were in the range of 200 pg of TEQ per egg. A disadvantage of these protocols is the relatively long assay time (several weeks).

The Japanese medaka (*Oryzias latipes*) is a small fish that is convenient for laboratory assays because it is easily reared in captivity, it can be induced to lay eggs in the laboratory all year round, and its larval envelope is transparent, permitting easy evaluation of developmental toxicity in addition to mortality. Wisk and Cooper[200]

studied the survival of Japanese medaka embryos to 3 days post-hatch, after exposing the embryos to the test chemicals within 1–2 h after fertilization. The LC_{50} for TCDD was 13 ng L^{-1} (40 pM) nominal concentration and, as in mammalian systems, the congeners that were fully chlorinated in the 2-,3-,7-, and 8-positions were substantially more toxic. An AhR-mediated mechanism of toxicity is apparent in that neither lethality nor morphological change is seen until after the formation of the liver,[201] and lethality occurs in the same concentration range as AHH induction.[202] In addition to synthetic DLC mixtures, Harris et al.[203] have demonstrated that lipophilic extracts from rainbow trout taken from Lake Ontario are embryotoxic to the Japanese medaka.

The effect of DLCs on the immune systems of intact animals has been known for many years; a dose-dependent reduction in thymic weight in rodents is observed. This was shown to be an AhR-mediated response by correlating the immunotoxic activities of different DLCs with their ability to induce monooxygenase enzymes.[204,205] Numerous interactive effects on these end-points involving TCDD and PCB congeners have been reported,[183,205–208] yielding evidence that certain PCB congeners can mask the activity of TCDD. Smialowicz et al.[209] treated mice with TCDD and PCB 153, alone or in combination, and examined both thymus weights and the ability of their spleen cells to form plaques upon treatment with SRBCs. PCB 153 alone had little effect on either end-point, but depending on its dose it could either enhance or suppress the responses of TCDD. Such complex interactive effects make it unlikely that a broadly useful bioassay for DLCs could be developed, using these end-points.

5 CELL PROLIFERATION ASSAYS

Knutson and Poland[210] developed an assay system for TCDD based on culturing the XB keratinocyte cell line, which is derived from a mouse teratoma. When cultured at low cell density in the presence of lethally irradiated 3T3 fibroblasts as feeder cells, the XB cells replicate and differentiate to give characteristic flattened, keratinized cells that are identifiable both by their shape and because they stain red with the dye Rhodanile Blue. At high cell density, the XB cells replicate but do not keratinize. However, low concentrations of TCDD cause the high-density cultures to keratinize in a dose-dependent fashion; therefore, the extent of keratinization can be correlated with the intensity of color development when the cells are stained. Keratinization requires a minimum concentration of TCDD of 50 pM; additionally, the efficacy of keratinization by a PCDD congener roughly parallels its binding affinity for the AhR, and thus suggests that this is a mechanism-based assay. This assay was shown to be applicable to other DLCs such as TCAB. A drawback to the assay is the relatively long incubation time that is required (nearly 2 weeks), which militates against the use of the assay for following the progress of a remediation ''on the fly''.

A variant of the keratinization assay, introduced by Gierthy and Crane,[211] employed a strain of XB cells denoted XBF. These do not keratinize in the presence of TCDD, but during a 14-day incubation form ''cobblestone-like'' cells (flat cells) that can be visualized by staining. The DL in this assay is 10 pM TCDD in the culture medium, with PAHs having 10^3–10^4-fold less response than TCDD. The flat-cell assay correlated linearly with chemical analysis by GC/MS for a series of soot samples that were contaminated with PCDFs.[121] It showed semiquantitative agreement with chemical analysis for the DLC content of a range of fish tissue and sediment samples[212] and of several transformer fluids.[213]

As a related end-point, one of the most characteristic and well-documented responses of halogenated aromatic compounds in humans is chloracne, caused by hyperkeratosis of squamous skin cells.[214] This end-point can also be seen in experimental animals such as rabbits and hairless mice. Indeed, an early example of a bioassay for DLCs was the production of chloracne in the rabbit pinna.[215]

One of the characteristic responses of DLCs is an increase in cell proliferation, which is linked mechanistically to a change in the binding between the epidermal growth factor and its receptor.[216,217] Cancers induced by TCDD also appear to be principally those of epithelial cells.[210,216]

6 CONCLUSIONS

Present regulations establish allowable concentrations of DLCs either on the concentration of TCDD or the total TEQ of named congeners, based in each case on congener-specific analysis. Under these circumstances bioassays can never replace an ''absolute'' analytical method such as GC/MS because they do not provide chemical identification. However, an inexpensive and rapid bioassay can usefully act as a screening tool based on a ''cut-off'' TEQ, to eliminate negative samples from further analysis. This could greatly reduce costs, especially if most samples are expected to have low levels of contamination and the assay has a low rate of false positives.

We have noted that AhR binding assays and immunoassays tend to have high false-positive rates (a ''conservative'' feature) because they respond to substances that bind to the receptor (or Ab) without causing toxicity. A

critical limitation occurs when screening assays have a significant rate of false negatives, which imply incorrectly that a contaminated sample is ''clean''. Enzyme induction and porphyrin accumulation are examples of assays in which one DLC may mask (antagonize) the dioxin-like activity of another, and an analyst cannot be confident that the TEQ obtained from the assay is a true reflection of the TEQ of the sample. Such assays are of limited value in screening programs unless interacting analytes are independently known to be absent; however, they may remain viable options for monitoring the progress of a remediation project.

The question of biological relevance always arises with an assay based on a biological principle. Whereas human health concerns might be addressed by an enzyme induction assay, preferably using a human cell culture, protection of fish in an aquatic environment might suggest an early life stage assay to monitor the potential for reproductive or developmental abnormalities. It is unrealistic to imagine that a single procedure will be applicable to all situations.

ABBREVIATIONS AND ACRONYMS

Ab	Antibody
AHH	Aryl Hydrocarbon Hydroxylase
AhR	Aryl Hydrocarbon Receptor
ALBS	Aryl Hydrocarbon Receptor Ligand Binding Subunit
ANOVA	Analysis of Variance
AP	Alkaline Phosphatase
ARNT	Aryl Hydrocarbon Receptor Nuclear Translocator Protein
ATP	Adenosine Triphosphate
CALUX	Chemically Activated Luciferase Gene Expression
CAT	Chloramphenicol Acetyl Transferase
DL	Detection Limit
DLC	Dioxin-like Compound
DMSO	Dimethyl Sulfoxide
DRE	Dioxin Response Enhancer
ECOD	7-Ethoxycoumarin-*O*-deethylase
ELISA	Enzyme-linked Immunosorbent Assay
EROD	7-Ethoxyresorufin-*O*-deethylase
GC/MS	Gas Chromatography/Mass Spectrometry
HAP	Hydroxyapatite
IR	Infrared
MFO	Mixed-function Oxidase
MS	Mass Spectrometry
NADPH	Reduced Nicotinamide Adenine Dinucleotide
NMR	Nuclear Magnetic Resonance
P450RGS	P450 Reporter Gene System
PAH	Polycyclic Aromatic Hydrocarbon
PCB	Polychlorinated Biphenyl
PCB 52	2,2′,5,5′-Tetrachlorobiphenyl
PCB 77	3,3′,4,4′-Tetrachlorobiphenyl
PCB 105	2,3,3′,4,4′-Pentachlorobiphenyl
PCB 114	2,3,4,4′,5-Pentachlorobiphenyl
PCB 118	2,3′,4,4′,5-Pentachlorobiphenyl
PCB 126	3,3′,4,4′,5-Pentachlorobiphenyl
PCB 128	2,2′,3,3′,4,4′-Hexachlorobiphenyl
PCB 153	2,2′,4,4′,5,5′-Hexachlorobiphenyl
PCB 156	2,3,3′,4,4′,5-Hexachlorobiphenyl
PCB 169	3,3′,4,4′,5,5′-Hexachlorobiphenyl
PCDD	Polychlorinated Dibenzo-*p*-dioxin
PCDF	Polychlorinated Dibenzofuran
PROD	7-Pentoxyresorufin-*O*-deethylase
QSAR	Quantitative Structure–Activity Relationship
RBA	Relative Binding Affinity
SDGC	Sucrose Density Gradient Centrifugation Analysis
SPFC	Splenic Plaque-forming Cell
SRBCs	Sheep Red Blood Cells
TCAB	3,3′,4,4′-Tetrachloroazobenzene
TCDD	2,3,7,8-Tetrachlorodibenzo-*p*-dioxin
TCDF	1,2,7,8-Tetrachlorodibenzofuran
TEF	Toxic Equivalency Factor
TEQ	Toxic Equivalence
UP-III	Uroporphyrin III
2,4,5-T	2,4,5-Trichlorophenoxyacetic acid
3-MC	3-Methylcholanthrene

An overview of current analytical methodologies for the determination of dyes in environmental samples is presented. Conventional analytical methods involving liquid chromatography (LC) and mass spectrometry (MS) with thermospray (TSP) interface are reviewed as well as the newly developed methods using atmospheric pressure ionization (API) interfaces. The combination of capillary electrophoresis (CE) with MS as a new alternative for the analysis and confirmation of polar compounds (and particularly the sulfonated azo dyes) in environmental samples is also discussed. Finally, the extraction and preconcentration of dyes from water samples involving various solid-phase extraction (SPE) cartridges are commented upon.

1 INTRODUCTION

Large quantities of dyes are produced for diverse applications, including textiles, paper, paint pigments, printing inks, and food coloring. According to recent information, nearly 20% of the world dye production, which rose more than 10% annually to 2.2 billion lb in 1994, is manufactured in Western Europe.[1] The textile industry is the largest consumer of these products, accounting for two-thirds of the dyestuff market. Since intermediates and degradation products of synthetic dyes can be potential hazards owing to their toxicity or carcinogenicity, they are of major environmental interest.

The analysis of dyes poses special problems because these products do not belong to a single group of chemical compounds, but encompass many chemical functionalities with large differences in solubility, volatility, ionization efficiency, and other properties. Additional complications in the analysis of sulfonated azo dyes exist because some of the manufacturing precursors to dyes are carried over to, and are not removed from, the final product. The result is a complex mixture containing the dye itself and several other interfering compounds.

In the nomenclature of dyes it is important to differentiate between dye classification and dye use. Dye classification is based on the major chromophore functionality of the dye, the main classes being azo (including the sulfonated azo dyes), anthraquinone, polymethine, phthalocyanine, sulfur, arylmethane, stilbene, and coumarin dyes. The use of a dye generally refers to the manner in which it is applied. Some of the most common applications are in acidic or basic media, as mordants, lakes, pigments, solvents, or dispersants. Figure 1 shows some typical structures of the main groups of dyes.

Dyes which are widely used in the textile industry to color natural fibers, may possess acid groups in their chemical structure. Especially, sulfonic acid groups are often present as sulfonate anions and provide very good water solubility. Recent estimates indicate that approximately 12% of the synthetic textile dyes used each year are lost to waste streams during manufacturing and processing operations and that 20% of those losses will enter the environment through effluents from wastewater treatment plants.[2] These compounds are difficult to remove in water-treatment procedures and, because of their high water solubility, they can be transported from municipal sewers through to rivers. In addition, dyes have been shown to undergo reduction in natural waterways and the environment and the degradation products include amines, which are known to be carcinogenic. Their presence in effluents and industrial wastewaters is of considerable interest because of their potential to contaminate groundwater and drinking water supplies.[3] Therefore, the detection, identification, and quantification of dyes at low levels in the aquatic environment is important for the protection of natural waters.

Most dyes are nonvolatile and thermally unstable, and consequently cannot be analyzed by gas chromatography (GC). For this reason, LC/MS was applied to the analysis and confirmation of the dyes. Current official analytical

methods for disperse azo dyes, e.g. United States Environmental Protection Agency (USEPA) 8321A,[4] are based on preconcentration methods followed by TSP/LC/MS, but are not applicable for sulfonated azo dyes (see Table 1). Problems were encountered with this interface for this kind of compound.[5]

With the development of API LC/MS interfaces, good sensitivity and structural information can be achieved as compared with other LC/MS interfacing devices such as TSP or particle beam (PB).

CE is a powerful alternative to classical chromatographic techniques for the separation of polar and ionic analytes because of its high separation efficiency and low solvent costs. It can be useful for overcoming the problems of LC in the separation of sulfonated azo dyes. In this respect, a major objective of the analytical chemistry

program at USEPA's National Exposure Research Laboratory (Las Vegas) is to foster and advance the adoption of new environmental monitoring technologies, especially those suited to pollutants for which conventional analytical approaches fail. An analytical separation technique that has enormous potential for environmental analysis is CE.[6] One of the broad areas of great potential for CE in environmental monitoring is outlined in the goals adopted by USEPA and set forth in its Environmental Technology Initiative (ETI) formulated in 1993. Under ETI, environmental monitoring technologies are sought that offer continuous monitoring capabilities, are inexpensive, are exportable to foreign countries, are low generators of waste, minimize exposure of personnel to hazardous chemicals, and address a broad range of analytes. These widely divergent goals could be easily addressed by CE in its various formats.

An overview of the current analytical methods for the determination of dyes in environmental matrices is presented, and aspects such as sample extraction and preconcentration strategies are also discussed.

2 LIQUID CHROMATOGRAPHY/MASS SPECTROMETRY

Most azo dyes are nonvolatile and thermally unstable compounds and consequently they cannot be analyzed directly by GC. Therefore, USEPA has validated a method[4] for several azo dyes and anthraquinone dyes, not including sulfonated azo dyes. The method is based on LC with ultraviolet (UV) and/or TSP/MS detection. Prior to analysis by high-performance liquid chromatography (HPLC) the target analytes are extracted by liquid–liquid extraction with methylene chloride for water samples or methylene chloride–acetone (1 : 1) for solid samples.

Some problems exist in the determination of sulfonated azo dyes by LC/TSP/MS and are discussed below.

Other LC/MS interfaces for the determination of sulfonated dyes have been tested such as the PB. Straub et al.[7] studied the mass spectra of some azo dyes including four solvent dyes, nine disperse dyes (one of which was a diazo dye), and one acid dye (the disulfonated azo dye Acid Orange 10).

With an HPLC/MS system using a PB interface it is possible to record the electron ionization (EI) mass spectra and gain useful structural information on these dyes. In addition, in some instances, additional organic impurities derived from decomposition, the coupling reaction process, or from external sources during the handling of commercial products, could be identified by HPLC/PB/MS. Characteristic fragmentation in azo dyes included cleavage of the C–N bonds on either side of the azo linkage, and cleavage of the N=N double bond with transfer of one or two hydrogen atoms, to form an imine or amine, respectively. Most azo dyes showed a molecular ion, and fragmentation from ring cleavage was observed. Naphthol-containing azo dyes presented $[M - CO]^+$ and $[M - HCO]^+$ fragment ions, which are not very intense but characteristic of a hydroxyl group on an aromatic ring. The acid sulfonated azo dye showed a spectra which indicated that complete desulfonation (m/z 246) was thermally accomplished in the mass spectrometer, in addition to characteristic fragment ions of naphthol-containing azo dyes. Detection limits of the compounds studied were in the range 500 ng–5 μg but the exact detection limit for Acid Orange 10 was not reported. LC/PB/MS was found to be two or three orders of magnitude less sensitive than TSP. The reduction products of Acid Orange 10 were identified by Voyksner et al.[8] These products are formed in industrial sludge and can be more harmful than their precursors.

Several desorption ionization methods have also been used for the analysis of sulfonated azo dyes. Ventura et al.[9] studied the spectra of some sulfonated dyes used in the industrial area of Barcelona (Spain) by fast atom bombardment (FAB) MS, including nitro, monoazo, diazo, trisazo, oxazine, and anthraquinone dyes. The behavior of the studied dyes varied widely. Cationized molecular ions, cleavage of azo groups, and loss of sulfonate from protonated or cationized molecular ions were the major common features. HPLC fractions of real water samples were analyzed with quantification limits that ranged from several nanograms to the low microgram level. However, because of low sample purity, modern dyes cannot be analyzed using the above-mentioned direct-probe techniques. This problem can be solved with the combination of a powerful separation technique, such as LC/MS.

2.1 Thermospray

TSP is a widely effective LC/MS technique because it can handle conventional LC solvents and chromatographic flow rates into the MS system and provides ionization for nonvolatile or thermally unstable samples. Therefore, TSP has been applied to the determination of dyes. Ballard and Betowski[5] reported detection limits between 15 and 200 ng for several dyes belonging to six different classes with a TSP interface coupled to a triple-stage quadrupole. This technique worked well for some representative dyes of the azo, methine, arylmethane, anthraquinone, coumarin, and xanthene classes, but it was less effective for the sulfonated azo dyes.

The negative-ion TSP mode of operation was found to be less sensitive than the positive-ion mode by a factor of 10. Switching the filament on can be a way to improve the structural information of the TSP ionization, as shown by Voyksner[10] with azo, diazo, and anthraquinone dyes in wastewater and soil. Detection limits of 10 ppt and 100 ppb in wastewater and soil, respectively, were achieved. The commercial diazo and anthraquinone dyes proved to be very complex mixtures of nearly 40 alkyl-substituted dye components, making monitoring and identification of a particular dyestuff difficult.

Flory et al.[11] investigated various factors that could affect the TSP response for nine sulfonated azo dyes. They found that too high concentrations of ammonium acetate buffer suppresses the ionization of these anionic dyes since the more volatile acetate anion will eject instead of evaporation of the dye anion.

The sensitivity problem of the TSP interface in the analysis of sulfonated azo dyes has been investigated by several authors and different solutions were given. Yinon et al.[12,13] recommended the use of a wire repeller placed in the opposite side of the ion extraction funnel. An increase of about two orders of magnitude was obtained with the wire repeller and the spectra of several sulfonated azo dyes could be recorded. In some instances, losses of $NaSO_3$ and $2NaSO_3$ were observed in many sulfonated dyes with the replacement of these groups by hydrogen atoms. Rafols and Barceló[14] found that for Acid Red 14, which has two $NaSO_3$ groups attached to different rings, both groups were lost. For Acid Blue 113, Acid Red 1, Mordant Red 9, and Acid Yellow 23, with two sulfonated groups in different rings, loss of only one group could be found. Owing to the above-mentioned controversy, it was suggested that, apart from the fact that the SO_3 groups are attached to different rings, other reasons related to their chemical structure make it difficult to lose the second $NaSO_3$ group. Losses of Na^+ or $2Na^+$ are common in all sulfonated dyes with replacement of these groups by hydrogen atoms. As an example, the TSP spectra of Acid Red 73 are shown in Figure 2.

The repeller-activated collisionally induced dissociation (CID) mass spectra of some dyes[15] was also compared with those obtained by TSP/MS with CID and

Figure 2 Spectra of Acid Red 73 with TSP/MS positive ionization (PI) and negative ionization (NI).

by EI. Common ions were found between these ionization modes.

McLean and Freas[16] modified a TSP/LC/MS system in order to improve the sensitivity for the analysis of some dyes by restricting the vaporizer exit orifice and adding a needle-tip repeller to the ion source. An increase in signal response was achieved for disulfonated azo dyes in the negative-ion mode. The TSP mass spectra contained mainly $[M - Na]^-$, $[M - 2Na]^{2-}$ and $[M - 2Na + H]^-$ ions.

Quantitative determination of disperse azo dyes has been carried out in a municipal wastewater treatment plant. The investigation of the fate of disperse azo dyes in the activated sludge process was the main objective of the study. Although the identification of two major reduction products of Disperse Red 1 by TSP/MS/MS could be achieved by Betowski et al.,[17] the mechanism of this reduction was unclear. Limits of detection of 180 pg for Disperse Red 1 in selected reaction monitoring could be achieved.

In summary, we can conclude that TSP gives, in most cases, poor structural information (tandem mass spectrometry (MS/MS) can be a solution for this problem) apart from molecular weight and some losses, e.g. SO_3^- from sulfonated azo dyes.

With reference to sensitivity, although most classes of dyes can be analyzed, good detection limits for monosulfonated and specially for polysulfonated azo dyes are difficult to achieve.

2.2 Atmospheric Pressure Ionization Interfaces

There are several interfaces which are classified as API interfaces, and that are given different names, but all of them have common features.[18]

Figure 3 Flow injection/ESP mass spectra of 100 ng μL^{-1} of Acid Orange 10 at collision activated dissociation (CAD) voltage of (a) −100, (b) −200 and (c) −300 V.

API techniques of pneumatically assisted ionspray (ISP) and electrospray (ESP) have been used for the analysis of dyes.[19,20] ESP achieves the best sensitivity for compounds that are already charged in solution.[21] For this reason the initial work with ESP/MS focused on ionic dyes such as sulfonated azo dyes which were difficult to analyze by PB or TSP, as was shown in the work of Straub et al.[7] While the disulfonated azo dye Acid Orange 10 showed a weak $[MH - 2Na + 2H]^+$ ion in TSP ionization, and underwent considerable thermal degradation in EI with a PB interface, ESP in the negative-ion mode was able to detect characteristic anions formed in the solution. The negative-ion ESP spectra of this dye were recorded under three capillary–skimmer potential differences of −100, −220, and −300 V (see Figure 3). Lower potential differences resulted in the formation of singly charged ions $[M - Na]^-$, $[M + H - 2Na]^-$, and a doubly charged $[M - 2Na]^{2-}$ ion. Higher potential differences resulted in more fragmentation with some losses in sensitivity. The base peak at m/z 151 $[HOC_{10}H_4(SO_3)_2 + H]^{2-}$ disappeared and $[M - 2Na - SO_3 + H]^-$ and SO_3^- ions at m/z 325 and 80, respectively, appeared from cleavage of a sulfonic group. The ESP/MS detection limit in negative-ion operation under full-scan MS conditions was 10 ng. In contrast, positive ESP ionization of Acid Orange 10 showed an almost 50-fold lower sensitivity. Only a weak $[M + Na]^+$ ion was identified at positive potentials of 100, 240, and 300 V.

Rafols and Barceló[14] studied the spectra of 11 sulfonated azo dyes by negative ISP ionization. They found an optimum extraction cone voltage of 20 V to obtain the maximum sensitivity and enough fragmentation to have structural information. The detection limits for the compounds studied varied between 1 and 80 ng. All the

Table 2 Calibration data obtained with LC/ESP/MS in time-scheduled SIM/NI mode for the studied dyes

Compound	m/z	Calibration equation	r^2	Linear range (ng)	LOD (ng)	LOQ (ng)

SIM/PI, Selected ion monitoring/positive ionization.

dyes in this study were acid compounds and only the negative-ion mode of detection was used. Additionally, calibration graphs with acceptable correlation coefficients were obtained, demonstrating that quantification is feasible with LC/API/MS techniques. Calibration equations for ISP interfaces in the range 1–80 ng and 600–800 ng, depending on the compound, were calculated. The authors also studied the calibration graphs by using a heated pneumatic nebulizer interface (or atmospheric pressure chemical ionization (APCI) interface). This interface provides more structural information than ion evaporation, and can handle chromatographic flow rates up to 1–2 mL min^{-1}. The technique was found to be less sensitive than the ISP interface with the exception of Mordant Red 9, a sulfonated dye that exhibits COONa and OH groups that give the molecule a much more basic character and showed better sensitivity in the PI mode. Tables 2 and 3 show the calibration data and detection limits for the studied dyes obtained with LC/ESP/MS and LC/APCI/MS in the PI mode. Figure 4 shows the LC/MS traces using LC/APCI/MS (in PI and NI mode) and LC/ISP/MS interfaces. Poor sensitivity, lower than 20–50 times, in less volatile disulfonated azo dyes versus monosulfonated dyes were reported in previous studies.[22] A better nebulization in the interface described by Rafols and Barceló[14] was attributed to the differences. The sensitivities of disulfonated dyes were lower than those of monosulfonated ones by a factor of 10 for ISP in both studies.[14,22]

Ballantine et al.[23] found that amine bases sensitize sulfonated azo salts towards ESP/MS. This has the effect of increasing the intensity of these ions by one to two orders of magnitude. It is proposed that the base enhances the removal of associated cations. This combines any ion peak series (from the different number of removed cations) into a single acid ion peak for each charge state (z), i.e. only the $[M - t\mathrm{Na} + (t + z)\mathrm{H}]/|z|$ ions would be observed. Once all cations have been removed, protons may associate with the compound to balance the removal of positive charges. The number of protons observed to associate with an ion depends on the final overall ion charge (z). The cation removal is not fully understood, but is thought to be influenced by the gas-phase proton affinity.

A relevant study was published by Lee and Henion[24] They used thermally assisted ESP to detect a hexasulfonated dye (Direct Red 80) of molecular weight 1240. The mass spectrum showed only multiply charged ions ranging from $[M - 6H]^{6-}$ to $[M - 2H]^{2-}$. They also worked on the determination of several polysulfonated azo dyes[25] by LC/ISP/MS which produced abundant $[M - Na]^-$ and $[M - 2Na]^{2-}$ ions with good sensitivity according to the number of sulfonic acid substituents.

In summary, the use of ESP in the NI mode offers higher sensitivity for sulfonated azo dyes than other techniques, e.g. APCI. Although APCI achieves more fragmentation, negative ESP ionization offers enough structural information which can be obtained either by increasing the extraction voltage or by using MS/MS.

Figure 4 LC/APCI/MS (PI and NI) and LC/ESP/MS (NI) and time-scheduled selected ion monitoring (SIM) conditions of a mixture of dyes at 30 and 3 ppm, respectively.

3 CAPILLARY ELECTROPHORESIS

Analytes for CE include ionic compounds and nonvolatile analytes such as dyes, especially those that are not

amenable to GC and that offer problems with LC separations, such as certain dyes. Nonvolatiles of interest in the environment include ecological indicators of stress or health, biomarkers of exposure, and surfactant molecules whose metabolites act as hormone modulators that can affect wildlife and humans. A closed-circle dilemma derives from the knowledge that many of these compounds are not regulated, and therefore there is no urgent need for their monitoring. Conversely, such compounds are not monitored only because effective methods for their identification and quantitation do not exist. A partial resolution to this circle is to develop research methods for these problematic compounds to assess their occurrence, action, and fate in the environment. Such data would ultimately serve as the basis for regulation and risk reduction. Sulfonated dyes are not regulated and the use of CE can be of help in developing a routine analytical technique for monitoring them.

Recent applications of CE in the analysis of dyes are discussed here.

3.1 Capillary Electrophoresis/Ultraviolet Detection

In general, CE separation is based on the different electrophoretic mobilities of ions, and can be influenced by several parameters, e.g. pH and electrolyte concentration. In the case of dyes, the separation is often difficult to accomplish by varying the pH because they may have moieties that are strong acids. Therefore, two methods have been applied to adjust the electrophoretic mobility for the separation of six sulfonated azo dyes and other related compounds.[26] Complexation by bis-tris-propane (BTP) and interaction with linear polymers added to the buffer and acting as pseudophases were performed. A buffer system based on BTP containing poly(ethylene glycol) (PEG) and polyvinylpyrrolidone permitted the separation of all analytes. Retention of the dyes caused by the polymeric additives was related to the analyte structure. It was demonstrated that the relative decrease in the electrophoretic mobility of the dyes correlates with the number of benzoaromatic rings in the molecules. Other buffers with different micellar agents, e.g. borate at pH 8.3 with cholic acid, were employed for the determination of several sulfonated azo dyes and other classes of compounds.[27] Analysis using SPE of spiked water samples and recovery studies were also carried out. Burkinshaw et al.[28] used a micellar buffer system consisting of 10 mM $Na_2B_4O_7$ and 40 mM sodium dodecyl sulfate (SDS) at pH 9 to separate two sulfonated azo dyes with very similar structures and relative molecular weights, and also several anionic and cationic dye intermediates which could not be separated by a conventional buffer. Suzuki et al.[29] also used 10 mM SDS as micellar agent in a mixture of 25 mM sodium phosphate buffer and 25 mM sodium borate buffer (1 : 1) at pH 8.0 for the analysis of sulfonated azo dyes and xanthene dyes used as food additives in Japan. However, the isomeric dyes R-2 and R-102 were not separated with good resolution, and β-cyclodextrin instead of SDS was added to achieve a good separation. Although most of the authors reported that separation of dyes by free capillary zone electrophoresis (CZE) is not possible and micellar electrokinetic capillary chromatography (MEKC) has to be applied, in some cases these compounds have been successfully separated by CZE.[30]

Quantification studies were also done by Liu et al.[31] using a CZE method for the separation of six synthetic food colorants including four sulfonated azo dyes and one arylmethane dye. A linear relationship between the standard concentration and peak area (PA) of each of these dyes was obtained in the concentration range 2–50 ppm, with a correlation coefficient >0.995. The relative standard deviation (RSD) of the method was about 3% and the minimum detectable amount at a signal-to-noise ratio (S/N) of 3 for all six synthetic colorants was 3 ppm.

Calibration graphs for standard solutions of eight sulfonated azo dyes and for extracted groundwater samples spiked with the same compounds were also obtained by Schönsee et al.[32] Additionally, to evaluate the performance of the automated off-line SPE/CE/UV method, groundwater samples were spiked with mixtures of the eight dyes in the range 0.05–0.25 mg L^{-1}. The preconcentration procedure was carried out with a volume of 300 mL in order to achieve a calibration range from 10 to 50 mg L^{-1}. The LODs for the dyes ranged from 11 to 300 ppb. The regression equations were characterized by correlation coefficients > 0.95, and better LODs could be calculated, for a S/N of 3, for concentrations between 10 and 150 μg L^{-1}. Figure 5 shows the separation of the target compounds in spiked groundwater (3 mg L^{-1}); after off-line SPE, this allows the determination of all the dyes.

Detection limits between 11 and 300 ppb for 11 synthetic food colorants (including some sulfonated azo dyes) were achieved using CZE with the host–guest complexation effects of β-cyclodextrin.[33] A 300 μm i.d. capillary tube made of fluorinated ethylene–propylene copolymer in a hydrodynamically closed separation compartment was used for the analysis, accommodating 90-nL sample injection volumes, thus providing the above-mentioned detection limits. This CZE procedure was applied to several samples including a soft drink concentrate.

CE is especially useful for analyzing certain reactive dyes that HPLC often has difficulty in analyzing, such as the bifunctional β-sulfatoethylsulfone reactive dyes

Figure 5 Electropherogram (214 nm) of the separation of eight sulfonated azo dyes spiked in groundwater (3 mg L^{-1}) after off-line SPE with Isolute ENV+ cartridges. Separation was carried out with a buffer solution of 9.2 mM ammonium acetate and 0.05% Brij 35. Peaks: (1) Acid Blue 113; (2) Acid Red 73; (3) Acid Red 13; (4) Mordant Yellow 8; (5) Acid Red 1; (6) Acid Red 14; (7) Mordant Red 9; (8) Acid Yellow 23.

and the phthalocyanine-based dyes. CE was employed in testing the purity of reactive dye samples, monitoring the reactions (kinetic studies) of reactive dyes with nucleophiles, or analyzing colored effluents.[34] A variety of buffers were investigated and the optimum was found to be acetonitrile at a ratio of 1 : 9 in a micellar buffer system (10 mM SDS, 10 mM sodium tetraborate, and 6 mM potassium dihydrogenphosphate at pH 9.0). Detection was effected with an on-line ultraviolet/visible (UV/VIS) detector positioned at the cathode. A CZE method with UV detection was developed for screening black reactive dyes and black acid dyes, isolated from cotton and wool materials.[35] The dye components were identified by using a newly developed marker technique, employing phenylacetic acid, benzoic acid, and *meso*-2,3-diphenylsuccinic acid. With this marker technique the RSDs of the migration indices and the electrophoretic mobilities for the analytes were improved and were below 0.6%.

Other reactive textile dyes such as chlorotriazine and vinylsulfone dyes, and their hydrolysis products, have also been analyzed in several commercial dyebath samples and sewage effluents from a water-treatment plant.[36] In these samples the majority of the peaks could not be assigned to any known compound and it was concluded that it would be necessary to couple CE with MS.

3.2 Capillary Electrophoresis/Mass Spectrometry

A comparative study of capillary liquid chromatography (CLC) and CE on the separation of some sulfonated and other classes of dyes has been carried out.[37] MEKC provided excellent separation and quantification of synthetic dyes and was found to be complementary to reversed-phase CLC in the separation and in their ability to quantify and identify analytes. Recovery data for water and soil extraction were obtained by MEKC/UV detection. Although CLC was coupled with continuous-flow liquid secondary ion mass spectrometry (CFLSI/MS) for confirmation purposes, interfacing CE with the MS instrument using a coaxial arrangement as used in CLC was more difficult and only UV detection with CE was performed.

Ion evaporation appears to be the preferred ionization mechanism for on-line CZE/MS because separated components already exist as charged species in the CZE buffer. Furthermore, this ionization process is best-suited for species which exist as ions in solution, such as sulfonated azo dyes.

Continuous-flow (CF) FAB has been coupled to CE[38] with a coaxial interface to analyze aromatic sulfonic acids and some azo dyes. However, excessive band broadening and loss of separation efficiency occurred owing to the long transfer line to the FAB ion source and the high-vacuum requirements. The newly developed atmospheric pressure interfaces such as ISP produce a mild form of ionization described by Thomson and Iribarne;[39] it was first coupled to CE by Henion et al.[40,41] with a liquid-junction interface for determining sulfonated azo dyes. Detection limits range from high parts per billion to low parts per million. The correlation coefficient for the linear regression through the means of four levels of concentration of the dye injected was found to be 0.990 and the reproducibility for automatic injection could routinely be within 2–4%. The mass spectra of the azo dyes gave peaks $[M - nH]^{n-}$, depending on the number of sulfonic groups. CE tandem mass spectra of the deprotonated molecular parent ion showed a daughter ion at m/z 80 corresponding to the sulfonated ion. Three sulfonated azo dyes were detected at low parts per million in spiked wastewater extract monitoring the sulfonate ion at m/z 80.

Eight mono- and disulfonated azo dyes have recently been analyzed with a Beckman P/ACE CE system connected with a Micromass interface to a VG Platform MS instrument.[42] Spiked and extracted water samples were separated and determined for confirmation of the studied compounds and a typical chromatogram of the analysis of an extracted sample is shown in Figure 6. Water samples were analyzed at the 3 ppm level by monitoring one ion for each studied compound in order to achieve maximum sensitivity. Detection limits between 100 and 800 ppb were achieved, with the exception of Acid Red 73, which exhibited low response and could not be quantified. Compounds which co-eluted and were not resolved could be determined because ions with different m/z ratios were obtained. The spectra obtained

Figure 6 Total ion chromatogram (TIC) of a CE/MS electropherogram for an extracted spiked (3 ppm) water sample. Peaks: (1) internal standard; (2) Acid Red 73; (3) Acid Red 1 + Mordant Yellow 8; (4) Acid Red 13; (5) Acid Red 14; (6) Mordant Red 9.

by CE/MS were similar to those obtained with ISP ($[M - tNa + (t + z)H]$ ions, depending on the number of sulfonated groups (n) and the charge (z), and some losses of SO_3^- and COO^- groups). In a previous study in the same laboratory,[14] the spectra of one of the studied dyes were compared using both interfaces (Figure 7).

In summary, CE offers good resolution and better efficiencies than LC; the use of MEKC gives a wide variety of separations of components. This enables one to analyze neutral compounds in addition to strong acids and very polar compounds that are not amenable to GC or LC. However, further optimization is required when coupling CE with MS. Detection limits are less satisfactory than those obtained using LC/MS interfaces because of the low CE injection volumes.

4 SAMPLE HANDLING

Nielen has reviewed sample handling which included SPE from aqueous matrices containing acidic herbicides for analysis by CE.[43]

Because extremely small volumes of solutions are injected in CE (nominally picoliters to tens of microliters), preconcentration, cleanup, and on-line sample concentration must be addressed in the context of the analysis. By means of field amplification techniques, relatively large volumes can be injected without introducing intolerable peak broadening.

SPE has been used for preconcentration and cleanup of sulfonated azo dyes by several authors. Brumley and Brownrigg[27] extracted two sulfonated azo dyes (mono- and polysulfonated) and several aromatic-containing organic acids by means of Empore poly(styrene–divinylbenzene) (SDB) extraction disks and SPE cartridges (SCX cartridges). Spiked water samples were extracted by SDB disks, eluted in two ways (with organic aqueous solvent and with an ion-pairing agent) and the fractions obtained, were passed through the SCX cartridge. Extractions of solid samples were carried out by either sonification or Soxhlet methods; subsequently, the extracts were treated like the water samples. The recovery for the polysulfonated dye Triptan Blue from soil was only about 28% and was attributed to the complex structure of the dye. From water, this compound showed higher recoveries. In contrast, the monosulfonated dye Orange II could be extracted with good recoveries from both water and soil samples.

Other types of solid phases have been employed for sulfonated dyes, such as C_{18} cartridges and columns[22,25] that were eluted with aqueous organic solvents. C_{18} cartridges

Figure 7 Mass spectra of Mordant Yellow 8 with (a) LC/ISP/MS interface and (b) CZE/MS interface.

from J.T. Baker, which were eluted with solvent mixtures of methanol–water–triethylamine (TEA), gave recoveries that ranged from 87 to 103% for monosulfonated azo dyes and from 65 to 105% for disulfonated azo dyes.[22] With the C_{18} columns from J.T. Baker, eluted with methanol after preconditioning with ammonium acetate buffer, recoveries that ranged from 70 to 122%[25] were achieved.

The application of copolymers such as SDB was found to be most suitable for the SPE of very polar

Table 4 Recoveries obtained from 300 and 500 mL preconcentrated spiked groundwater samples (3 mg L^{-1}) by SPE with LiChrolut EN and Isolute ENV+ sorbents

Compound	LiChrolut EN			Isolute ENV+	
	100% MeOH 0.01% TEA	90% MeOH 10% H_2O 0.01% TEA	70% MeOH 30% H_2O 0.01% TEA	100% MeOH 0.01% TEA	80% MeOH 20% H_2O 0.2% TEA[c]
Acid Blue 113	N.D.[a]	N.D.	N.D.	N.D.	34 ± 7
Acid Red 73	39 ± 2	39 ± 1	32 ± 2	55 ± 4	83 ± 14
Acid Red 13	36 ± 2	40 ± 1	32 ± 1	71 ± 7	80 ± 11
Mordant Yellow 8	47 ± 3	49 ± 1	42 ± 4	64 ± 3	69 ± 7

[b] n.d. = not detected.
[c] Preconcentration of 500 mL of sample.

compounds.[44] Cross-linked polymeric sorbents with sulfonic functions, such as Isolute ENV+ and LiChrolut EN, were examined for their suitability for off-line preconcentration of the studied sulfonated azo dyes.[32] The recovery and standard deviation data obtained on processing 300 and 500 mL of spiked groundwater samples are reported in Table 4. Preconcentration with Isolute ENV+ using 100% MeOH (0.01%TEA) as eluent achieved recoveries up to 71%. The application of Isolute ENV+ for further optimizations was found to be more effective. Although the recoveries of Acid Yellow 23 and Acid Blue 113 were below 50%, for six dyes the recoveries could be improved to 64–83% by eluting with a mixture of 80% MeOH, 20% water, and 0.2% TEA.

More sorbents should be tested for extraction and preconcentration of dyes in various environmental water matrices. Polymeric sorbents with different polymer functionalities, e.g. sulfonation, seem to work better than silica-based phases. The development of immunoaffinity sorbents may lead to a solution to the problem of low recoveries for some of the more polar and ionic dyes. In general, it would be necessary to find sorbents that allow the percolation of large volumes of up to 1–2 L in order to reduce the LODs of CE techniques.

5 CONCLUSIONS

LC/MS has been shown to be a good method for the determination of dyes. In this respect TSP has worked well for several classes of these compounds, but it has shown poor sensitivity for sulfonated azo dyes. Some techniques were applied to improve the detection limits of these compounds, such as the use of a wire repeller or restricting the vaporizer exit, but the development of LC/API/MS interfaces, which provide more structural information and high sensitivity, can lead to more extensive use in environmental analysis,

[d] Combined with preconcentration.

replacing classical LC/MS interfaces. In particular, ISP can provide, with the manipulation of the cone voltage or combination with MS/MS, enough structural information and selectivity.

CE, with its different modes, shows several advantages for polar analytes and can be easily coupled with classical ESP interfaces because of the restricted flow rates. Sensitivity problems result from the small injection volumes and, therefore, preconcentration techniques should be applied. Limits of detection for the various techniques reported in this paper are shown in Table 5. More work needs to be done in the future and the focus will likely be towards the application of CE/MS combined with SPE. Owing to the high efficiency and diversity of separation in CE, and the fact that it is inexpensive and a low generator of waste, the technique will permit the required analytical performance for determining sulfonated azo dyes in environmental waters to be achieved.

The interest in analytical procedures for explosives residues in environmental media steadily increases as more and more formerly utilized military sites are certified and converted to full- or part-time civilian use. Careful statistical studies have clearly demonstrated that analyses based on randomly collected "grab" samples of soils frequently produce a false picture of the extent of explosives contamination. Well-designed sampling plans, which

Encyclopedia of Analytical Chemistry

employ multiple samples taken from small areas and which consider the distribution of the soil particles, are mandatory for understanding the true extent of contamination. Because site remediation is such a costly venture, there is a strong need for analytical procedures which are capable of quantitating explosives in soil and groundwater samples quickly and accurately, using equipment and methods which may be operated reliably by nontechnical personnel. For that reason, scientific interest is gradually moving away from the completely laboratory-based, statistically validated, and highly technical standardized methods, such as high-pressure liquid chromatography (HPLC) and gas chromatography (GC) and their mass spectroscopic analogs, towards the many fieldable analytical techniques. Some of these, such as ion mobility spectrometry and the various magnetic resonance techniques, are still in their infancy; their potential and utility are still to be fully developed. Others, such as the colorimetric and enzyme-based field test kits, have been fully tested and, in some cases, have been adopted as standard methods themselves. Still others, such as the various mass spectrometric methods, involve highly technical equipment which must be simplified before it can be used routinely in the field. However, the extreme sensitivities characteristic of these state-of-the-art instruments partially offset the need for extensive operator training. A variety of mass spectrometric techniques may yet be used routinely for explosives residue analysis in the field. Some of these new methods may be used in, or even be derived from, forensic applications.

1 INTRODUCTION

1.1 Chemical Classes of Explosives

Nitrogen-containing explosives and their transformation products detected in the environment are almost always of military origin and fall into three distinct classes. The *nitroaromatics* are related to 2,4,6-trinitrotoluene (TNT, CAS 118-96-7), and include the following species: 1,3,5-trinitrobenzene (1,3,5-TNB, CAS 99-35-4); 1,3-dinitrobenzene (1,3-DNB, CAS 99-65-0); methyl-2,4,6-trinitrophenyl nitramine (tetryl, CAS 479-45-8); 2,4-dinitrotoluene (2,4-DNT, CAS 121-14-2); 2,6-DNT, (CAS 606-20-2); 2-amino-4,6-dinitrotoluene (2-Am-DNT, CAS 33572-78-2); and 4-amino-2,6-dinitrotoluene (4-Am-DNT, CAS 19406-51-0). The *nitramines*, which are typically more energetic than the nitroaromatics, include the two heterocyclic compounds hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX, CAS 121-82-4) and octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine (HMX, CAS 2691-41-0). The *nitrate esters* are represented by nitroglycerine (NG, CAS 55-63-0) and pentaerythritol tetranitrate (PETN, CAS 78-11-5). The physical properties of these species are summarized in Table 1[1,2,3] while their structures are presented in Figure 1. The chemical names and common acronyms of additional explosives have been tabulated in Beveridge.[4]

Ammonium picrate (ammonium 2,4,6-trinitrophenoxide, CAS 131-74-8 AP) was the principal explosive used in a number of armor-piercing shells, bombs, and rocket warheads from the early 1900s until after World War II. While AP is no longer manufactured, wastes containing this component are still encountered at military installations in the United States. Picric acid (2,4,6-trinitrophenol, CAS 88-89-1 PA) is both an explosive and a common industrial chemical with uses that include dyeing fabric and leather, glass coloration, and metal etching.[5]

The scope of this review focuses on the analysis of *organic* explosives in the environment. A discussion of the properties and determination of the inorganic explosives, such as water gels and ammonium nitrate fuel oil, has been omitted intentionally.

1.2 The Origin of Explosives in Contaminated Soil

The contamination of soil with explosives frequently resulted from historical – and now both outdated and unapproved – disposal practices from manufacturing, spills, ordnance demilitarization, lagoon disposal of explosives-contaminated wastewater, and open burn/open detonation (OB/OD) of sludges from explosives processing, waste explosives, excess propellants, and unexploded ordnance. Facilities that may be contaminated with explosives include active and former manufacturing plants, ordnance works, army ammunition plants, naval ordnance plants, army depots, naval ammunition depots, army and naval proving grounds, burning grounds, artillery impact ranges, explosive ordnance disposal (EOD) sites, bombing ranges, firing ranges, ordnance test and evaluation facilities, etc. A number of these facilities have high levels of soil and groundwater contamination, although waste disposal was discontinued 20 to 50 years ago. Common munitions fillers and their associated secondary explosives include Amatol (ammonium nitrate/TNT), Baratol (barium nitrate/TNT), Cyclonite or Hexogen (RDX), Cyclotols (RDX/TNT), Composition A-3 (RDX), Composition B (TNT/RDX), Composition C-4 (RDX), Explosive D or Yellow D (AP/PA), Octogen (HMX), Octols (HMX/TNT), Pentolite (PETN/TNT), Picratol (AP/TNT), Tritonal (TNT), Tetrytols (tetryl/TNT), and Torpex (RDX/TNT).[6] The United States has characterized 30 large and medium sized TNT-contaminated sites at federal facilities; together, they contain over one million cubic yards of contaminated soil. The total number of smaller sites contaminated with TNT is not yet known,

but it is reported that the army alone has on the order of 2000 explosive-contaminated sites that may require remediation,[7] and more exists at navy and air force facilities. Similar patterns of contamination are found throughout Europe and the former Soviet Union.[8] Evaluating sites potentially contaminated with explosives is necessary to carry out US Department of Defense, United States Environmental Protection Agency (USEPA), and US Department of Energy policies on-site characterization and remediation under the Superfund, Resource Conservation and Recovery Act (RCRA), Installation Restoration, Base Realignment and Closure (BRAC), and Formerly Utilized Defense Site (FUDS) environmental programs.

1.3 The Origin of Explosives in Contaminated Groundwaters

Groundwater may be contaminated with explosives in two distinct ways. The first is a direct consequence of the disposal of munitions wastes during World War I, World War II, the Korean War, and the Viet Nam War. Unlined lagoons, which could not contain species such as munition charges, were frequently employed. Leached mobile contaminants migrated with groundwater at several installations. The second involved the disposal of washwaters used to clean equipment and interior surfaces at munition manufacturing and demilitarization facilities. It has been estimated that up to 2×10^6 L of this type of wastewater is generated daily from a single production line. Current practice is to collect washwater from these processing operations in a holding tank and periodically pump it through a series of carbon adsorption columns prior to discharge to surface streams. Standard practice allows monitoring of explosives concentrations between columns to prevent contamination downstream. These point discharges are subject to state and federal National Pollutant Discharge Elimination System (NPDES) permits that generally limit the acceptable concentrations of TNT and RDX. Although carbon adsorption technology can reduce TNT and RDX to low part per billion levels, which meet present discharge limitations, these carbon columns have finite lifetimes. Eventually, breakthrough occurs and regeneration or replacement is necessary. Ground- and surface-water contamination may therefore occur immediately prior to replacement of the carbon adsorption water treatment columns.[9]

1.4 Regulatory Limits for Explosives in Groundwater and Soil

The USEPA, in collaboration with the Oak Ridge National Laboratory, has published a series of health advisories and recommended water criteria for several explosives-related chemicals, as summarized in Table 2.[2,3,10] These values for the nitroaromatics range over two orders of magnitude between 2,6-DNT ($0.0068\,\mu g\,L^{-1}$ water)[11] to TNT ($1.0\,\mu g\,L^{-1}$ water).[12] If the criterion for HMX ($400\,\mu g\,L^{-1}$ water)[13] is also included, the range spans four orders of magnitude. The criteria for 2,4-DNT ($0.17\,\mu g\,L^{-1}$ water),[11] RDX ($2.0\,\mu g\,L^{-1}$ water),[14] and 1,3,5-TNB ($1.0\,\mu g\,L^{-1}$ water)[15] are intermediate. No general recommendations have been issued for contaminant levels in soil. Instead, soil levels have been evaluated on a site-by-site basis, depending on such factors as the proximity of the contaminated soil to locations of groundwater use. For example, at Cornhusker Army Ammunition Plant, cleanup criteria of $5\,\mu g$ TNT g^{-1} soil, $10\,\mu g$ RDX g^{-1} soil, and $15\,\mu g$ TNB g^{-1} soil were established.[16]

[a] Plastic-bounded explosive.

To compound the problem of toxicity, explosives are remarkably persistent in the environment when they are initially present at elevated concentrations. A study was performed at Los Alamos National Laboratory to determine the half-lives of various explosives in the soil in a temperate climate.[17] The samples contained 0.1% w/w of one of twelve explosives mixed with soil in a blender. Samples were then placed in transite cylinders with fine-mesh stainless steel screen

on the bottom and hardware cloth over the top, then buried in the test area outdoors with their tops flush with the surrounding surface. The explosives were therefore subjected to naturally occurring temperature fluctuations, rainfall, and bacterial decomposition over a period of twenty years. Estimates of the half-lives were made from normalized ultraviolet (UV) chart data by applying first-order rate equations. The results of these tests are summarized in Table 3,[17,18] and demonstrate that the half-life of various explosives in soil can range between 1 year (for TNT) to 92 years (for PETN). The half-lives of plastic-bonded explosives exceed 100 years.

It should be emphasized that the Los Alamos results applied to (a) very substantial concentrations of explosives which were (b) mixed artificially with soils to create samples. Other investigators have emphasized that the degradation behavior of low concentrations of explosives in contaminated soils found in the environment frequently exhibits a strikingly different behavior. For example, Rodacy et al.[19] exposed small masses of authentic contaminated soil samples containing 10 ppb TNT or RDX in shallow dishes to sunlight outdoors. The concentration of TNT was undetectable after 60 days, while that of RDX was essentially unchanged. Observations such as these suggest that the degradation of low concentrations of explosives such as TNT in soil may proceed by mechanisms other than first-order kinetics. Special handling may be needed to assure that such concentrations in soil remain stable until the sample is actually analyzed. The entire issue of determining ''holding times'' for explosives in soil samples is discussed in section 2.2, entitled ''Maximum Holding Times (MHT) for Soil and Aqueous Samples''.

2 SAMPLING CONSIDERATIONS

2.1 Special Considerations for Soil Sampling

The traditional approach for sampling soils which may have been contaminated with explosives is to use ''grab'' samples, taken from a wide area. These samples would then be analyzed using appropriate field or laboratory-based procedures. The resulting data would be used to evaluate the level of explosives contamination and to choose the appropriate cleanup procedure(s). Careful thought would suggest that random grab sampling might not be the most appropriate strategy. An implicit assumption in this approach is that the distribution of contaminants is sufficiently homogeneous that the results from the analysis of these discrete samples can be used to represent average site conditions within the grid. In general, the number of discrete samples collected is insufficient to address the short-range distribution of contaminants and, practically speaking, all samples are automatically assumed to be representative of average site conditions within the grid from which they were collected.[20] Furthermore, the environmental characteristics of explosives-related compounds in soil indicate that they are extremely heterogeneous in spatial distribution. Concentrations range from nondetectable levels (<0.5 ppm) to percent levels (>10 000 ppm) for samples collected within several feet of each other. In addition, the waste disposal practices at these sites, such as OB/OD, exacerbate the problem and may result in conditions ranging from no soil contamination up to solid ''chunks'' of bulk high-explosives, such as TNT or RDX. Secondary explosives concentrations above 10% (>100 000 ppm) in soil are of concern because of potential reactivity that affects sampling and materials handling processes during remediation.[21] Often, 70–90% of soil samples analyzed during an explosives site investigation do not contain detectable levels of contamination.[22] Jenkins et al. observed that:

> Accurate chemical characterization of a hazardous-waste site requires the development and implementation of a well-designed sampling plan. After defining the area of interest [target population(s)], which might be an entire site or several defined areas within a site, samples are collected according to one of several possible schemes. Distributions of contaminants are very site specific, depending on the manner in which the contamination occurred, the physical and chemical properties of the contaminants involved, soil type, and the geology and hydrogeology of the site. Because of these site-specific characteristics, many references recommend that one perform a preliminary study before devising a sampling plan. [Reprinted by permission of John Wiley & Sons, Inc., © 1997 from T.F. Jenkins, C.L. Grant, G.S. Brar, P.G. Thorne, P.W. Schumacher, T.A. Ranney, *Field Analyt. Chem. Technol*, **1**, 151.]

Beginning in 1996, Jenkins et al.[23] systematically investigated the degree of short-range heterogeneity in analyte concentrations present at explosives-contaminated sites. Soil was sampled at nine locations on three installations. At each location, seven discrete grab samples were collected in a wheel pattern of radius 61 cm (one sample from the center and six equally spaced around the perimeter). Each of the seven samples was homogenized in the field and duplicates were analyzed by both an on-site colorimetric method (USEPA SW-846, Method 8515, ''Colorimetric Screening Method for TNT in Soil'')[24] as well as an off-site standard method (USEPA SW-846 Method 8330 ''Nitroaromatics and Nitramines by High Performance Liquid Chromatography''),[25] both described elsewhere in this article. Portions of the seven discrete samples were

also used to form a composite sample which was analyzed by both procedures. TNT concentrations obtained from both types of analysis varied by as much as two and a half orders of magnitude within a sampling wheel. Partitioning of overall variances for data indicated that sampling error dominated over analytical error. Therefore, the probability of collecting discrete samples that represent average analyte concentrations is very unlikely with these levels of heterogeneity. Results from analysis of composite samples, however, exhibited mean concentrations representative of the average condition, as well as low relative standard deviations (RSDs), indicating that field homogenization was adequate for characterization.

These results[20] exhibit several unifying themes that can be applied in designing future investigations of explosives-contaminated sites. First, it is clear that there was extreme heterogeneity at all sampling locations. A single sample from any of the 122-centimeter diameter circles could differ by orders of magnitude or more from the mean concentration of the small area sampled. RSDs for the seven discrete samples were often greater than 100%. A second consistent finding was that composite samples of the seven discrete samples could be reliably homogenized and subsampled on-site. This also opens the possibility of compositing discrete samples representing a larger area if concentration variations suggest that this approach would be desirable. Most importantly, it permits on-site processing without elaborate apparatus.

Jenkins et al.[20] summarized the shortcomings of the grab sampling approach as follows:

> Although random grab sampling is appealing from a cost perspective, it may be totally inadequate for decisions about the need for, or adequacy of, remediation. To provide data that can satisfy this need with a high level of confidence, the total uncertainty associated with site characterization must be understood and reduced to acceptable levels. ... For these four locations [as described in reference 20], standard deviations due to analysis, whether on-site or laboratory, were always much lower than the corresponding deviations due to sampling, and hence total error was dominated by sampling error. For the other locations, sampling error was even greater and so overwhelmed analytical error that this type of fractionation would only be possible with the use of asymmetric (here, logarithmic) limits. Clearly, if we want to make a significant improvement in the quality of site-characterization data, the major effort should be placed on reducing sampling error. Single grab samples are totally inadequate. [Reprinted by permission of John Wiley & Sons, Inc., © 1997, from T.F. Jenkins, C.L. Grant, G.S. Brar, P.G. Thorne, P.W. Schumacher, T.A. Ranney, *Field Anal. Chem. Technol*, **1**, 159.]

The results presented above needed to be expanded by evaluating additional explosives, sites, and sampling strategies. Jenkins et al.[26] described such additional work performed on soil samples at an active firing range located at Canadian Force Base (CFB)-Valcartier, Quebec. The principal contaminant, HMX, was present at concentrations about two orders of magnitude greater than TNT, even though the munition fired at this site had a 70 : 30 ratio of HMX to TNT. The authors again observed that sampling error frequently exceeded analytical method error by at least tenfold, and that more precise analytical results would be obtained only when more representative samples were taken. Several approaches were recommended to address this problem, such as on-site homogenization, compositing of discrete samples, and on-site analysis with appropriate confirmation results at an off-site environmental laboratory.

Additional work which evaluated the effect of sampling depth and novel sampling patterns was performed at the Ft. Ord, CA, firing range.[27] The contamination at Ft. Ord, like that at CFB-Valcartier, originated from antitank rockets. Hence, the contamination was not random. Depth profiling was performed using manual excavation for 0–15, 15–30, 30–45, and 45–60 cm, and a post-hole digger for 105–120 cm. Analysis of these soils showed that by far the greatest concentration of HMX was in the 0–15 cm depth range, with minimal penetration to lower levels. The authors also noted that the vast majority of explosives contamination was centered near the tank targets, rather than being distributed uniformly or near-uniformly throughout the site. The investigators observed:

> Since much of the site is free of significant explosives residue, it is inappropriate to estimate a mean concentration for a large area. Instead, sampling should concentrate on surface soils around target locations, to define the boundaries of contamination. To demonstrate this point, the concentrations of HMX in surface soils were plotted as a function of distance from the target along with similar data from CFB-Valcartier. With concentrations decreasing as distance from the target increases, a logical sampling strategy would use concentric rings with the target at the center. Such rings might employ radii varying by 3 to 5 m. Eight or more sample points would be located equidistant from each other around each ring, which would allow two composite surface samples to be formed for each ring. Each discrete sample should contain about a kilogram (±200 g) of soil and be homogenized thoroughly prior to subsampling for formation of composites. Each composite would contain one-half of the sampling points chosen in an alternating pattern. Results of this work demonstrate that EOD personnel can efficiently collect soil samples for site characterization at the same time that they are clearing the site for unexploded ordnance. Since the major portion of the explosives residues at the inland ranges are in the surface soils, samples for additional characterization should be relatively easy to collect. The depth of contamination in specific areas can be determined iteratively after the extent of surface contamination is mapped. M.E. Walsh, P.G. Thorne, P.H. Miyares, T.A. Ranney, C.L. Grant, J.R. Esparza, *Site Characterization for Explosives Contamination at a Military Firing Range Impact Area*, Special Report 98-9, 21–22, 1998.]

An unexpected observation from the Ft. Ord study was the effect of very small particles on bulk measured concentrations of HMX. A large amount of fine dust was noted when very dry bulk samples were homogenized and subsampled. Analysis of two samples of dust showed HMX concentrations two to three times higher than that for the bulk soil. Apparently, a substantial portion of the explosives residues are associated with very fine particles that are not bound to the bulk sands. Clearly, there is danger of loss of these fine particles during mixing and subsampling.

2.2 Maximum Holding Times for Soil and Aqueous Samples

The ''MHT'' is the longest interval that a sample, aqueous or soil, may be stored prior to analysis before its analyte concentration is reduced by an unacceptable level or percentage. USEPA procedures specify a maximum pre-extraction holding time of seven days at 4 °C in the dark, to be consistent with the MHT values of other organics in soil.[28] One study[29] described the determination of the MHT in uncontaminated soils and aqueous matrices. The soils were taken from three totally unrelated sources, viz. (a) standard soil obtained through the US Army Toxic and Hazardous Materials Agency; (b) Captina silt loam from Roane County, TN; and (c) McLaurin sandy loam from Stone County, Mississippi (MS). Similarly, the aqueous samples were also drawn from three independent sources, viz.: (a) reagent-grade water; (b) groundwater from the Oak Ridge National Laboratory Aquatic Ecology Facility; and (c) surfacewater from the headwaters of White Oak Creek on the Oak Ridge Department of Energy Reservation. Aliquots of soil or water were spiked with explosives as required, then stored and analyzed as described in the reference.

The two statistical definitions used to determine the MHT were specified by the American Society for Testing and Materials (ASTM)[30] and Environmental Science and Engineering, Inc. (ESE) for a holding time study conducted in co-operation with the USEPA.[31] Both definitions are based on an approximating model for predicting concentration with time. The ASTM defines the MHT as the time the predicted concentration falls below the lower two-sided 99% confidence interval on the initial concentration. The ESE defines the MHT as the time the one-sided 90% confidence interval on the predicted concentration falls below a 10% change in the initial concentration. The difference between the two definitions is the method of placing a lower bound on the initial concentration. The ESE MHTs are usually longer than the ASTM MHTs because decreasing the initial concentration by 10% is usually a larger reduction than the lower two-sided 99% confidence limit. The ASTM MHT definition is recommended for analytical methods with precision such that the lower bound on 99% confidence limit for an analyte concentration is less than 10% of the initial concentration. Otherwise, using the ESE MHT definition would be more conservative. The results of the study on MHT for four explosives in both aqueous and soil matrices are summarized in Table 4; the calculated MHT are all considerably longer than those recommended by the USEPA.

Table 4 Recommended MHT for four munitions in soils and water

Munition	Storage condition (°C)	Matrix type	Recommended MHT (days)
HMX/RDX	4	Groundwater	50
HMX/RDX	4	Surface water	30
TNT	4	Groundwater	16
DNT	4	Groundwater	4
TNT/DNT	4	Surface water	14
HMX	4	Soil	52
RDX	4	Soil	63
TNT[a]	−20	Soil	233
DNT	4	Soil	107

[a] Immediate freezing recommended.

Grant et al.[32] provided additional MHT values not only from dry spiked soil, but also authentic contaminated soils from the Rockeye site at the Naval Surface Warfare Center (NSWC) at Crane, IN. The latter soils contained measurable concentrations of HMX, RDX, TNT, TNB, two isomeric microbiological transformation products of TNT, viz., 2-Am-DNT and 4-Am-DNT, and 3,5-dinitroaniline (3,5-DNA), a microbiological transformation product of TNB. The blank soils employed in this study were obtained from Windsor (VT), Charlton (NH), and Ft. Edwards (NY). All soils were spiked with explosives dissolved in water to eliminate any acetonitrile effects. The results on spiked soils showed that RDX and HMX are stable for at least eight weeks when refrigerated (2 °C) or frozen (−15 °C) but that significant transformation of TNT and TNB can occur within two hours without preservation. Freezing provides adequate preservation of spiked 2,4-DNT for eight weeks or longer. The results on field-contaminated soils did not show the rapid transformation of TNT and TNB that was observed in the spiked soils, and refrigeration appeared satisfactory.

Presumably, the explosives still present in the field soil after many years of exposure are less biologically available than in the spiked soils.[6] An earlier related study[33] demonstrated that explosives in spiked, air-dried soils are stable for a 62-day period under refrigeration. Data from the Grant et al.[32] study indicate that air drying of field-contaminated soils may not result in significant losses of explosives contaminants. Explosives in air-dried soils are stable at room temperature if they are kept in the dark.

Most of the analytical procedures for explosives in soils employ acetonitrile extracts, which are expected to be stable for at least six months under refrigeration. Acetone extracts are also thought to be stable if they are stored in the dark under refrigeration. The latter solvent is normally not recommended because it enhances the photodegradation of explosives.[6]

3 DETERMINATION OF EXPLOSIVES IN AQUEOUS SAMPLES

3.1 Procedures Employing "Salting-out" Liquid–Liquid Extraction Followed by High-pressure Liquid Chromatography

The most traditional extraction procedure for isolating explosives from aqueous samples involves the liquid–liquid extraction of the sample with a nonpolar solvent such as dichloromethane. Leggett et al.[34] evaluated this approach critically and proposed a superior alternative based on "salting-out" the explosives from a sample. Briefly, 130 g of sodium chloride was dissolved in 400 mL aqueous sample, to which 100 mL acetonitrile was then added. After the mixture was shaken vigorously in a separatory funnel, the layers were allowed to separate. Under these conditions, the final volume of immiscible acetonitrile was 22 mL, allowing a preconcentration factor >16. Individual component recoveries for a wide variety of nitroaromatics, nitroesters, and nitramines ranged between 93 and 100%. The authors confirmed that recoveries were not dependent on analyte concentration over at least a 200-fold range in concentration, and the presence of chloride in the acetonitrile phase had no effect on analyte retention times (see below).

The most widely-used method for separating and detecting extracted explosives employs HPLC with UV absorbance detection at 254 nm. The analytes are separated on an octyl (LC-8, 25 cm × 4.6 mm, 5 μm particles, product of Supelco, Inc., Bellefonte, PA) column using a water–methanol–acetonitrile (50 : 38 : 12 v/v/v) eluent (1.5 mL min^{-1} flow rate). Such a configuration permitted the major target analytes, viz. HMX, RDX, TNT, and 2,4-DNT, to be separated from the following species: TNB; SEX (1-acetyloctahydro-3,5,7-trinitro-1,3,5,7-tetrazocine, CAS 13980-00-2); TAX (1-acetylhexahydro-3,5-dinitro-1,3,5-triazine, CAS 14168-42-4); 2,6-DNT; 2-Am-DNT; 4-Am-DNT; 2,6-diamino-4-nitrotoluene (2,6-Dam-NT, CAS 59229-75-3); 2,4-diamino-6-nitrotoluene (2,4-Dam-NT, CAS 6629-29-4); and 2,4,5-TNT.[10] When a typical 100 μL sample injection was employed, the detection limits were 26, 22, 14, and 10 μg L^{-1} for HMX, RDX, TNT, and 2,4-DNT, respectively. These values were initially calculated using three times the standard deviation of the detector baseline noise, and were later confirmed using formal calculations based on the method of Hubaux and Vos.[35] Such calculations employ not only replication but also user-specified estimates of both false-positive and false negative errors (typically 5% for each). This analytical procedure was later modified to employ a methanol–water (1 : 1) eluent with the same flow rate. A related confirmation procedure employed a bonded cyano HPLC phase (LC-CN) column (25 cm × 4.6 mm, 5 μm particles, Supelco) with identical mobile phase, flow rate, detector, and monitoring wavelength. The two aforementioned separations provide almost exactly opposite analyte retention orders, resulting in a powerful tool for analyte identification.

The HPLC-based-procedures described above were validated using a collaborative study involving nine independent laboratories.[36,37] The four test matrices employed represented uncontaminated, treated, fortified, and authentic contaminated matrices. Based on the overall excellent performance of the HPLC procedures, they were ultimately adopted as standard methods for the analysis of nitroaromatic and nitramine explosives in water by the Association of Official Analytical Chemists (AOAC) and the USEPA, and in soil by AOAC, ASTM, and the USEPA.[1,28]

The HPLC methods described above may be modified slightly to enable either improved separation of specific analytes or improved reliability of identification. For example, two pairs of aminodinitrotoluenes (2-Am-DNT and 4-Am-DNT) and diaminonitrotoluenes (2,4-Dam-NT and 2,6-Dam-NT) cannot be resolved using the LC-CN column alone. However, all constituents may be baseline resolved by using two columns, viz., a short octadecyl column (LC-18, 3.3 cm × 4.6 mm i.d., 3 μm particle size, Supelco) and a traditional cyano column (LC-CN, 25 cm × 4.6 mm i.d., 5 μm particle size), placed in series. The separation employs a ternary eluent (water–methanol–tetrahydrofuran, 60.5 : 25 : 14.5 v/v/v) with a flow rate of 1.5 mL min^{-1}.[38] The use of HPLC in combination with photodiode-array detection is advantageous, because peak identification is more reliable with additional information from the UV spectrum. Further, by comparison of the various UV spectra at the peak front edge, peak apex, and peak end edge, one

can determine whether a single component is, indeed, present, or whether contaminants are co-eluting with the analyte of interest. Emmrich et al.[39] studied the separation of 21 nitroaromatics and nitramines in a single run using HPLC and reported both absorbance maxima λ_{max} and the molar absorptivities ε_{max} for each analyte. The authors used a Merck LiChrospher 100 RP-18 column (25 cm × 4 mm i.d., 5 μm particle diameter) and mobile phases employing (a) methanol–water (1 : 1 v/v, isocratic elution), (b) methanol–water gradient elution, or (c) methanol–water containing 2% v/v tetrahydrofuran, gradient elution. All analytes were eluted and resolved using the gradients, but TNT and nitrobenzene (NB) almost co-eluted. The presence of a small volume of tetrahydrofuran enabled these two particular analytes to be resolved cleanly. The HPLC method of Caton and Griest[40] was developed to quantitate the transformation products of TNT which would be observed during composting. This procedure uses an RP-C_{18}/Anion Mixed-Mode reverse phase/anion exchange column and three eluents: (a) 90 : 10 water–methanol v/v solution that was 0.015 M in potassium phosphate; (b) methanol; (c) acetonitrile. Two independent gradient programs were developed and evaluated. Quantitations were performed employing the UV absorbance at 254 nm. The aminodinitrotoluenes were baseline-resolved successfully using a single column.

3.2 Procedures Employing Solid-phase Extraction

The "salting-out extraction" (SOE) procedures described above were clearly successful for removing and concentrating explosives from aqueous samples, but they also exhibited several distinct disadvantages. First, each extraction generated a considerable volume of chemically hazardous waste. Second, liquid–liquid extractions in general may produce emulsions which may or may not clear easily with time. Third, concentration factors greater than approximately 25 would be difficult to achieve without either substantial volume reduction of the acetonitrile extract or the use of very large (>2 L) aqueous sample volumes. The extraction of such large sample volumes using traditional liquid–liquid extraction glassware becomes unwieldy. Taken together, it is worthwhile considering procedures based on solid-phase extraction (SPE), where the aqueous sample passes through a small cartridge or disk containing an appropriate medium which has been conditioned with organic solvent. After the disk or cartridge is dried, the explosives are eluted with a small volume, typically not more than 5 to 10 mL, of organic solvent.

Maskarinec et al.[41] evaluated the extraction properties of three SPE media, viz. XAD-4, Porapak® R (vinyl pyrrolidone, Waters Corporation), and Porapak® S (vinyl pyridine, Waters), which were packed into small columns and conditioned initially using acetone and water. Fortified aqueous samples (500 mL) were pumped through each column, and explosives were removed using 10 mL acetone under gravity flow. Acetone was exchanged for ethanol prior to HPLC analysis.

The presence of explosives was monitored using both UV and liquid chromatography/electrochemical detectors (LC/ELCD). The sensitivity of the former was approximately 1 μg mL^{-1} ethanol extract for HMX, RDX, TNT, 2,4-DNT, and 2,6-DNT when the monitoring wavelength was 254 nm. The LC/ELCD (−1.0 V vs Ag/AgCl reference electrode) had several notable advantages and disadvantages compared to the complementary UV detector. The LC/ELCD exhibited approximately tenfold better sensitivity for explosives than the UV detector.[42] Furthermore, the detector response would be proportional to the number of nitro groups present on a given analyte. Hence, the LC/ELCD was ideal for detecting potentially unidentified by-products and transformation products of explosives with at least some selectivity. In addition, LC/ELCD was superior to the UV detector for monitoring species such as NG and PETN. These compounds absorb weakly at 254 nm and strongly at 210 nm, where substantial interferences are well-known. As a worst-case example, the estimated detection limits of NG using the UV detector (254 nm) and LC/ELCD were 160 ng and 0.38 ng, respectively.[43] On the other hand, the LC/ELCD was considerably less robust than the UV detector. Oxygen had to be removed scrupulously from both the final ethanol extract and the eluent. The gold substrate and mercury-film electrode had to be prepared carefully and refreshed frequently due to contamination from irreversibly adsorbed species.

Overall, the two Porapak® resins outperformed XAD-4 as an extraction medium for explosives. They behaved in a manner consistent with specific adsorption of nitro compounds, in that the breakthrough volume was nearly equivalent for the test analytes HMX, RDX, TNT, and DNT. Even SEX and TAX, two very polar explosives by-products, were retained quantitatively.

Jenkins et al.[10] compared the characteristics of the SOE with two SPE media, viz. cartridge-based Porapak®-R and Empore® styrene–divinylbenzene disks, both conditioned with acetonitrile and water. The data collected over a four-day evaluation period were used to calculate certified reporting limits (CRL) according to a statistically unbiased procedure.[44] The CRL values are tabulated in Table 5. In general, none of the procedures were consistently superior to the others in low concentration detection capability. The only CRL value that appears out of line is that for tetryl determined using membrane-SPE, 0.83 μg L^{-1}. Inspection of the data

Table 5 CRL for various preconcentration techniques

Analyte	CRL ($\mu g\,L^{-1}$)		
	Salting-out (SOE)	Cartridge SPE[a]	Membrane SPE[b]
HMX	0.19	0.21	0.33
RDX	0.13	0.27	0.12
TNB	0.052	0.042	0.051
DNB	0.081	0.032	0.036
Tetryl	0.20	0.24	0.83
TNT	0.086	0.068	0.13
2-Am-DNT	0.10	0.046	0.055
2,4-DNT	0.083	0.085	0.044
o-NT	0.13	0.10	0.20
p-NT	0.22	0.12	0.23

[b] Using Empore® styrene–divinylbenzene disks conditioned with acetonitrile, then water.

NT, nitrotoluene.

indicated that this high CRL was caused by low recovery on only one of the four certification days. Elevated CRL values for tetryl were noted by other workers who attributed this behavior to the instability of the analyte in water. The present authors suggested that this instability is due to photochemical decomposition. The study also included the evaluation of 58 groundwater samples taken for method comparison from the Rockeye site at the Naval Surface Warfare Center (NSWC) in Martin County, IN.

Overall, the results may be summarized as follows:

- The three methods were comparable with respect to low-concentration detection capability, ranging from 0.05 to 0.30 $\mu g\,L^{-1}$.
- Percent recoveries generally exceeded 80% except for HMX and RDX by membrane-SPE, where recoveries were lower.
- Large interferences were found on about half of the groundwater samples from the NSWC, using the two SPE methods, but none were found by SOE.
- The SPE interferences were traced to a matrix interaction of the SPE polymers with low pH groundwaters which apparently caused the release of unreacted monomers or other contaminants from the interior of the polymer.

At least partly in response to the problems identified above, several manufacturers of SPE materials sought to improve the retention of very polar organics such as HMX and RDX, and experimented with new cleaning procedures to better remove interferences from these materials. As a result, Waters Corporation released a new ultra clean SPE material for use in cartridge SPE under the name Porapak® RDX (ultraclean divinylbenzene-vinylpyrrolidone), and 3 M Corporation developed a new surface modified styrene divinylbenzene membrane which had also been cleaned more extensively (Empore® styrene–divinylbenzene ''reverse-phase sulfonated'', or SDB-RPS).[45,46] The latter is a modified phase which provided additional retention for polar organics such as HMX.

Porapak® RDX cartridges were evaluated extensively, as described in Bouvier and Oehrle.[47] High-purity water samples fortified to 1 or 10 ppb in each of 14 explosives or explosives-related products were extracted using cartridges which had been preconditioned with acetonitrile and water. The concentrated explosives were eluted with a small volume of acetonitrile, which was subsequently diluted to 40% with high-purity water, vortexed, and analyzed by HPLC (variable wavelength detection). The recoveries of all 14 analytes, ranging from the polar HMX and RDX to the nonpolar 2,4-DNT and 2,6-DNT, exceeded 89% with RSDs of less than 7%.

Walsh and Ranney[48] recently and independently compared the performance of the Waters Sep-Pak Vac Porapak® RDX cartridges with Empore® (SDB-RPS) extraction membranes. The cartridges were conditioned using acetonitrile followed by water; the membranes were conditioned with acetone, isopropanol, methanol, acetonitrile, and finally water. After passage of each water sample through the solid-phase, air was drawn through the solid phase for 15–20 min to remove as much residual water as possible. The explosives were eluted from the solid phases with 4–5 mL acetonitrile. Final separation and quantitation of each analyte was performed using a gas chromatograph equipped with an electron capture detector (ECD) using the specific modifications noted in the reference. The authors specifically noted that calibration curves employing linear models were not appropriate for quantitating explosives when the ECD was employed. Instead, a quadratic model with all terms statistically significant, not only was more satisfactory but also allowed a greater concentration range to be covered. Furthermore, low concentration trinitroaromatic standards were unstable even when left in amber vials at room temperature. When the autosampler tray was cooled, these concentrations were stable during a typical 12-hour shift. The average recoveries observed from the two extraction media were entirely comparable for water samples spiked to 5 and 10 $\mu g\,L^{-1}$ in each of nine explosives, regardless of whether gas chromatography with electron capture detection (GC/ECD) or HPLC was used as the final quantitating method, and ranged between 85 and 136% for all analytes and both quantitating methods.

Table 6 MDL for target analytes using GC/ECD[a]

[a] 1-L water samples fortified to $10\,ng\,L^{-1}$ preconcentrated to 4.0 mL acetonitrile using either cartridge or membrane SPE.

[b] MDL greater than the spiked concentration and therefore not valid.

The method detection limit (MDL)[49] for ten analytes, using the two SPE media and the GC/ECD method described, are presented in Table 6, and typically range between 3 and $20\,ng\,L^{-1}$ for each analyte, regardless of medium considered.

The same authors also quantitated the explosives present in authentic groundwaters drawn from wells at several military installations using both membrane and cartridge SPE media and GC/ECD with HPLC confirmation. The concentrations of each analyte ranged over five orders of magnitude; in the specific case of TNT, the concentrations spanned 0.1 and $10\,500\,\mu g\,L^{-1}$. In all cases, virtually identical values were obtained using either extraction procedure and either method of determination.

3.3 Determination of Explosives in Seawater

The determination of explosives in seawater provides a challenging extension to those methods applicable to groundwater. For many years, the disposal of obsolete munitions was performed by merely dumping them in the ocean. In 1963, the United States Navy initiated a program in which obsolete Maritime Administration hulks were used for this purpose. These old Liberty ships were loaded with munitions and scuttled at sea.

One of the first procedures for determining explosives in this matrix involved the extraction of 100 mL seawater with benzene followed by evaporation of the resulting extract under reduced pressure. Quantitation was performed by GC/ECD, employing injection of 8–9 μL of concentrate onto a packed column. The limits of detection for TNT, RDX, and tetryl observed were estimated to be 2, 5, and 20 parts per trillion, respectively.[50] This procedure was used to determine TNT, RDX, and tetryl in seawater, sediment, and ocean floor fauna samples taken from an explosives dumping area 85 miles west of Cape Flattery, WA, and from similar samples taken 172 miles south-southeast of Charleston, SC, at a nominal depth of 2500 meters. No explosive contaminants were found in any of the samples examined.[51] Sediment samples were initially extracted with high-purity benzene. The solvent was subsequently evaporated completely, and the residues dissolved in 50 μL fresh benzene. Half of the concentrate was spotted along a ChromAr® 500 thin-layer chromatography sheet (glass fiber thin-layer chromatographic paper consisting of 70% Silicar TLC 7F containing a short wave, 254 nm, UV phosphor on 30% glass fiber), and developed with hexane–acetone (45 : 55 v/v) as eluent. The appropriate disks corresponding to the explosives were removed and re-eluted with benzene. Later, gas chromatographic analyses were performed on the final benzene concentrates. The limits of detection for TNT, RDX, and tetryl in tissues were determined by injecting 4.1×10^{-7} g TNT, 11×10^{-7} g RDX, and 17×10^{-7} g tetryl into a 51.4 g sea cucumber. After the usual subsequent workup and analysis, the figures of merit were estimated to be 47, 123, and 740 parts per trillion, respectively. The procedure for determining the detection limit was not given.

A very recent paper described the determination of explosives in seawater using solid-phase microextraction (SPME) fibers as the extraction medium, followed by quantitation using either HPLC or gas chromatography/ion-trap mass spectroscopy (GC/ITMS).[52] The test matrix initially evaluated was synthetic ocean water, prepared by dissolving an appropriate quantity of ''Instant Ocean'' (a commercially available product) into high-purity water. This test matrix was then spiked with 50 ppb in each of TNT, RDX, 2-Am-DNT, 4-Am-DNT, and 2,4-DNT. Four SPME fibers, which exhibited widely differing polarities, were evaluated: poly(dimethylsiloxane) (PDMS, 100- and 65-μm thickness, nonpolar); polyacrylate (85 μm film thickness, polar); and Carbowax–divinylbenzene (65-μm thickness, polar). All determinations were performed with a Finnigan MAT GCQ GC/ITMS operated in the negative chemical ionization (CI) mode, with methane as the reagent gas.

The study demonstrated clearly that no one fiber was suitable for all of the analytes; however, the most suitable fiber for general use was Carbowax–divinylbenzene. Two critical figures of merit were calculated and reported, viz., the limit of detection (LOD) and the limit of quantitation (LOQ). Both of these quantities are defined in terms of X, the mean blank signal, and σ, the standard deviation of the blank signal. The LOD values, calculated as $X + 3\sigma$, were in the low (5–10) part-per-trillion range for all of the target NT analytes, but greater for the nitramines.

The LOD and LOQ ($X + 10\sigma$) for RDX were 325 and 790 parts-per-trillion, respectively.

To test the utility of the developed method, both SPE and SPME were used for the analysis of several real oceanwater samples. Several pairs of samples, consisting of one-liter samples for SPE and 20-mL samples for SPME, were collected. The one-liter oceanwater samples were extracted through SDB-RPS SPE disks, which had been conditioned as described previously. The disks were washed with water, then ultrasonically extracted overnight with 4–5 mL acetonitrile. The recovered acetonitrile extract was then concentrated via nitrogen ''blowdown'' over a period of several hours to a final volume of 0.5 mL for HPLC and GC/ITMS analysis. The 20-milliliter oceanwater samples were separated into 5-milliliter aliquots for direct SPME sampling and GC/ITMS analysis.

The HPLC and GC/ITMS results using SPE generally agreed quite well for most of the samples. The SPME results, however, were often high compared to the SPE results. This behavior may be explained in several ways:

- The most probable explanation is that the SPE results may appear low due both to decreased extraction efficiency and losses in the lengthy analyte concentration/solvent evaporation process.
- The SPME results could appear high because SPME, with its fewer steps and sample transfers, may recover a greater portion of the sample.
- The accuracy of the SPME results may be biased high because the calibration curve was prepared using simulated oceanwater, while the samples contained real oceanwater. This is unlikely because ''Instant Ocean'' salt is designed to be an accurate surrogate matrix for seawater. The residual solvent ''tail'' in the gas chromatograms was significantly smaller when SPME, rather than disk SPE, was employed as the extraction method, as expected.

Caton and Barshick[53] examined various ways to improve the qualitative and quantitative determination of TNT and its reduction products in SPE extracts of seawater using the Finnigan GCQ instrument described previously. The authors were able to detect 10 pg of TNT, 2,4-DNT, RDX, 4-Am-DNT, and 2-Am-DNT with a signal-to-noise ratio exceeding 6 using a standard 1 μL injection when the instrument was operated in the negative ion chemical ionization (NICI) mode.

Darrach et al.[54] also investigated the use of SPME for ocean-related samples, including sediments which were contaminated with unexploded World War II-vintage undersea ordnance. This material was scattered in Halifax Harbor, Nova Scotia, Canada, after a minor fire in 1945 caused the detonation of a small nearby munitions bunker complex. The PDMS-divinylbenzene fiber exhibited the highest relative efficiency of the commercially available fibers for TNT extraction. After each extraction, the fiber was dried in a vacuum desiccator for at least 15 min. The analytes collected on the fiber were then desorbed and swept into a quadrupole mass spectrometer. Explosives detection was achieved using the reversal electron attachment detection (READ) method, which takes advantage of the NTs' extremely large cross-section for attaching zero-energy electrons. The explosives detected in this work were TNT and DNT in sediments, at concentrations ranging from the low parts-per-billion to high parts-per-trillion ($\mu g\,kg^{-1}$ to $ng\,kg^{-1}$).

Rodacy et al.[18] described the determination of explosives in raw seawater or acetonitrile extracts (from solid-phase disk extractions) of seawater using the ion mobility spectrometer (IMS). Approximately 100 samples containing 10 ppb TNT or 20 ppb RDX (0.3 μL injections) can be analyzed at the rate of three per minute before excess water must be vented from the system. Scatter gradually increases from ±10% of the nominal value at the beginning of the series to ±25% at the end of the series. The scatter is presumed to be due to the increased concentration of water in the drift region. With direct injection of seawater samples, a large deposit of salt builds up in the injection liner. If this deposit remains, it sorbs some of the analyte, resulting in broad ''stubby'' peaks.

A better method of analyzing seawater samples is to deposit the sample aliquot onto a quartz sample tube or filter paper, followed by evaporation of the water. The residual explosive is then thermally desorbed in the standard manner. This method eliminates the problem of salt build-up in the injector, permitting samples up to several hundred microliters to be analyzed routinely. One obvious disadvantage, however, is that water evaporation can be relatively slow (several minutes), which decreases the sample throughput. To partially overcome this limitation, several samples may be prepared simultaneously. Alternatively, one can use a more volatile solvent, such as acetonitrile and acetone, and significantly decrease the amount of time required for the solvent to evaporate.

Rodacy et al.[18] noted that the acetone or acetonitrile extracts of seawater were frequently colored, from light to dark yellow, and even further to a deep green. For the most part, the compounds responsible for the color did not interfere with the analysis. On one occasion, the authors reported that the water surface was covered with what appeared to be millions of small ($\frac{1}{4}$ inch and smaller diameter) jellyfish. On that one day, a chemical species in the extract, probably a jellyfish metabolite, was problematic.

The agreement between IMS and HPLC concentrations for explosives determined in the same extract was frequently excellent. At concentrations between 100 and 1000 parts per trillion (ppt), the IMS values averaged

42.2% less than the HPLC values determined using the standard Method 8330 (described in detail below). Between 1 and 100 parts per billion (ppb), the IMS values were 2.4% higher than the HPLC values. Between 100 and 800 ppb, the IMS data was 20.0% higher than the HPLC values. Overall, the IMS results agreed with the HPLC analysis within 7.3%, based on a data set representing nearly 200 samples.[55] IMS values appeared to be biased low compared to those generated in the HPLC analyses, possibly due to nonlinearity of the calibration curve. The major problems involved with the IMS included severe sensitivity to vibration and the lack of robust structural construction, leading to frequent instrument failures.

3.4 Additional Procedures

The foregoing discussion has emphasized the determination of explosives in water using HPLC because the analytes are not degraded thermally, as they would typically be if gas chromatographic methods were employed. The thermal lability of explosives places a potentially severe limitation on the use of GC-based methods, which would offer far greater potential sensitivity and selectivity than their HPLC counterparts. To address this problem, Yinon et al.[56] evaluated a gas chromatograph equipped with a septum-programmable injector, which permitted cool on-column injections. The mass spectrometric detector was deployed in both its electron impact (EI) and CI modes (reagent gas isobutane). Two groups of explosives were evaluated: (A) TNT, tetryl, RDX, HMX, and PETN; and (B) 2,3-, 2,4-, 2,5-, 2,6-, and 3,4-DNT. The test samples were prepared by spiking water with a mixture of explosives at the desired concentration, then extracting them with dichloromethane. The extracts were taken to dryness; the residues were dissolved in methanol and injected into the gas chromatograph. The authors noted that the nitramines RDX and HMX did not degrade in the injection port. Tetryl, a chemically unstable analyte, formed *N*-methylpicramide in the ionization source prior to ionization as expected,[57] but did not degrade further. The method enabled detection of 10 ppb TNT, RDX, HMX, and tetryl in water.

Feltes et al.[58] quantitated explosives in aqueous samples using a variety of gas chromatographic detectors, including mass spectrometric detectors in three different modes, viz. EI; positive-ion chemical ionization (PICI); NICI; ECD; and the chemiluminescent nitrogen detector (CLND), also known as the Thermal Energy Analyzer (TEA). SPEs of fortified one-liter water samples were performed with cartridges packed with resins (XAD-2, XAD-4, XAD-8) or silica-based SPE media (octadecyl, phenyl, cyano). The explosive analytes were eluted with a small volume of dichloromethane, which was later dried over anhydrous sodium sulfate and reduced in volume to about 1 mL in a rotary evaporator after exchange of the solvent to methanol.

The authors noted that while nitroaromatics can be determined successfully by ECD as a result of their high electron affinity, the response for nitroaromatics depends strongly on the individual compound. On the other hand, the CLND response is more similar for all the compounds because the nitrogen content of each analyte does not vary as sharply as the electron affinity. For example, the CLND response ratio of 3,4-DNT to 2-NT is 3.4, while the corresponding ECD response ratio is 61. The CLND exhibits excellent selectivity towards nitrogen-containing analytes, and is therefore better suited for the determination of explosives in complex environmental samples than the ECD, which is less selective. On the other hand, the ECD is approximately three orders of magnitude more sensitive than the CLND. The authors compare and contrast the merits of the various detectors as follows:

> As a result of their high electron affinities, nitroaromatic compounds can be determined with high sensitivity by GC using ECD. If, however, highly polluted surface water is to be investigated, ECD is not sufficiently selective for an unambiguous compound assignment. In contrast, a chemiluminescence detector is much more selective for nitro compounds, allowing a reliable peak assignment if reference compounds are available. The major disadvantage of the chemiluminescence detector is its lower sensitivity (compared with the ECD), which precludes the analysis of weakly polluted water. Definite compound assignment can usually be achieved with GC/MS (gas chromatography/mass spectrometry) where NICI is more sensitive and selective than EI, but gives fewer structure-specific fragments. One highly successful, but seldom-used, approach for improving the sensitivity of HPLC-based quantitations of explosives is to derivatize the analytes in a post-column reactor, such as that described in Engelhart et al.[59] Initially, the explosives were photolyzed by elution through a photo reactor consisting of 20 meters of crocheted Tefzel™ capillary tubing coiled around a low-pressure mercury lamp (254 nm). In the second step, the nitrite ion so generated is reacted with colorimetric reagents, such as sulfanilamide and [napthyl-(1)]-ethylene diammonium chloride, to form an azo dye whose absorbance can be monitored at 540 nm (via the Griess reaction, discussed in detail elsewhere in this chapter). Using this approach and nominal 5 to 10 μL injections, it was possible to detect selectively 25–50 ppb nitramines and 30–100 ppb of nitrate esters, even in complex mixtures. The detection limit for esters and nitramines was approximately 100 pg using the derivatization, compared to approximately

100 μg unreacted. Only for the nitroaromatic explosives is a UV detection system twice as sensitive as the detection system described here.

4 DETERMINATION OF EXPLOSIVES IN SOIL SAMPLES

4.1 Extraction Techniques for Explosives Residues in Soil: Initial Considerations

Many of the analytical procedures employed for the determination of explosives in aqueous samples may also be used for their analysis in soils. The most important difference between the overall methods is, of course, the exact procedure(s) employed to extract the analytes from the matrix. The explosives range in polarity from the moderately polar DNT and TNT to the highly polar HMX and RDX; hence, the choice of extraction solvent becomes an important variable. In addition, there are a variety of generally accepted procedures available for extracting solid samples, including Soxhlet extractors, ultrasonic baths, mechanical wrist-action shakers, and homogenizer–sonicators. Two very recent additions to this list are supercritical fluid extraction (SFE) and accelerated solvent extraction (ASE™).

Jenkins and Grant[60] performed an extensive optimization study for the extraction of explosives in soil. The test matrix, taken from the Iowa Army Ammunition Plant, was the surface of an old ordnance burning area that had not been used for several years prior to sampling. The extraction behavior of two soils and four analytes, viz., TNB, RDX, HMX, and TNT, were evaluated during this study. The authors noted that the solubilities of RDX and HMX were over twenty times higher in acetonitrile than in methanol; hence, acetonitrile was the preferred extraction solvent. The performance of acetonitrile was equivalent to that of methanol for TNT and TNB. Both solvents were suitable for the HPLC determinations which would be employed subsequently. The extraction techniques evaluated were Soxhlet, ultrasonic bath, mechanical wrist-action shaker, and homogenizer–sonicator. Both the Soxhlet extractor and ultrasonic bath recovered more than the homogenizer or shaker. The ultrasonic bath and shaker offered additional advantages to Soxhlet and homogenizer–sonicator in that several samples could be processed simultaneously.

The chromatographic separations of the analytes were performed using the HPLC methods described previously for groundwater samples. The explosives were eluted from the ''primary'' column (Supelco LC-8, 250 × 4.6 mm, 5 μm particle size) using a water–methanol–acetonitrile eluent (50 : 38 : 12 v/v/v, 1.5 mL min^{-1}). The ''confirmation'' procedures employed either a Supelco LC-CN or LC-18 column (both 250 × 4.6 mm) using 50 : 50 v/v water–methanol eluent.[61] LC-CN, which is frequently used as a ''normal'' phase column, was particularly effective for confirmation because the elution order was almost completely inverted from that observed for LC-8 and LC-18, which are both strictly ''reversed'' phase columns. Since few commercial laboratories are equipped to use either the electrochemical detector or TEA with LC (liquid chromatography), and the intent is to develop a method for general use, the authors concentrated on UV detection. A wavelength of 254 nm was chosen because a variety of manufacturers offer a fixed wavelength detector based on the mercury lamp emission line at 254 nm. All analytes of interest absorbed either strongly (nitroaromatics) or modestly (nitramines) at this wavelength, while potential interferences such as chlorinated organic compounds do not.

Overall, the sonic bath method is recommended because it is inexpensive and can be used to process a number of samples simultaneously and unattended. The gentle heating that occurs with the sonic bath (≈39 °C) also seemed desirable to increase the rate at which equilibrium is attained. The sonic bath does not suffer from the problem experienced with the Soxhlet device of co-extracting significant amounts of interfering substances that have a low solvent–soil partition coefficient. It is also worth noting that the Soxhlet extraction of thermally labile analytes such as tetryl frequently presents unexpected difficulties. On the other hand, there were some disadvantages and/or precautions to be noted in conjunction with sonic agitation. Analyte extraction efficiency may depend on the vigor of agitation, which depends on many variables for sonic devices. It had been observed that the extent of particle disruption varies inversely with solid/solution ratio; consequently this ratio should be constant in comparison analyses. Solvent variables such as viscosity, vapor pressure, and dissolved air concentration affect acoustic impedance. Not surprisingly, temperature increases allow cavitation bubbles to collapse with less force; consequently, the increased solubility may be offset by reduced agitation. However, as long as conditions are held constant, the sonic bath represents an excellent way to perform such extractions.

4.2 Experimental Considerations and Statistical Validation of the Proposed Standard Method

The procedure sketched above was subjected to a rigorous statistically constructed collaborative study involving eight independent laboratories.[33,62,63] An open-literature paper describing this study[64] thoroughly explained many of the critical experimental details. For example, air-drying of the soil samples away from direct sunlight for at least 24 hours prior to extraction minimized

concentration changes to due to photodegradation. It was recommended, but not required, that the soil sample be ground to pass a 30 mesh sieve prior to extraction. Weisberg and Ellickson[65] recommended that soil samples be inspected carefully prior to extraction. Extreme caution must be exercised if the samples arrive with a dry appearance. Raw munitions will appear as a grayish-white powder or pellets, mixed in with the solid matrix. Samples containing greater than 2% explosives should be neither ground nor sieved.

The authors carefully evaluated the use of the ultrasonic bath and the relevant extraction kinetics, which varied both with the specific analyte and soil considered. In general, extraction periods of less than 4 hours often recovered less than 80% of the total extractable analyte. An extraction of 18 hours, on the other hand, recovered greater than 90% of all the extractable analytes in a variety of field-contaminated soils. An 18-hour period was also convenient because the extraction could be started in the late afternoon and the extracts processed the following morning. The authors noted that the rate of analyte extraction from spiked soils was quite different than from field-contaminated soils. Despite the fact that the spiked soils were aged for two days to allow solvent evaporation and analyte interaction with the soils, only 15 min of extraction time was required for greater than 90% analyte recovery. Clearly it was unrealistic to develop extraction methodology based solely on spiked material. For these reasons, an 18-hour ultrasonic period with acetonitrile was employed. The recovery of tetryl at a bath temperature of 45 °C was significantly less than that at 11 °C; hence, the cooling and temperature of the ultrasonic bath demand particular attention.

Various soil-to-extraction solvent ratios were investigated, with the initial method evaluation performed using 2 g of soil to 50 mL acetonitrile. A ratio of 2 g soil to 10 mL acetonitrile was selected because it gave the best low-level detection capability. Higher soil-to-solvent ratios were not tested because sufficient volumes of processed extract were needed to allow both primary analysis and secondary analyte confirmation.

One of the clear potential advantages of using the ultrasonic bath was the ability to process large numbers of samples simultaneously. Such a practice, would, however, introduce the possibility of reduced sonic dispersion and extraction recovery. To test this possibility more carefully, 4 replicate, 2.0 g portions of contaminated soil were extracted for 18 hours as usual with no other tubes in the bath, and another 4 portions were processed in an identical fashion along with 32 additional samples in the bath. No significant differences were found between the two treatments at the 95% confidence level for any of the analytes.

Prior to analysis by LC, the soil extracts had to be filtered to protect expensive reverse-phase columns. Because of the long period of sonication required for maximum analyte recovery, the soil aggregates were dispersed into very fine particles with long settling times. These fine particles made filtration of the extracts extremely difficult, even after the extracts were centrifuged at 5000 rpm for extended periods of time. Rupturing of the membranes sometimes occurred due to the excessive pressure required. For this reason, additional steps had to be introduced to enable facile filtration of the acetonitrile extracts. Adding aqueous calcium chloride solution (optimized concentration 5 g calcium chloride L^{-1}) produced flocculation of the fine particles and rapid settling for most soils. After a 15-min settling time, the clarified solutions were readily filtered through 0.5 μm filters.

Stock standards of explosives dissolved in acetonitrile can be safely used for periods up to one year if they are stored in glass, at 4 °C, in the dark, and with precautions to minimize solvent evaporation. Working standards can be prepared and used over a 28-day period if refrigerated and kept in the dark when not in use. In general, extracts can be held for up to two months without large adverse effect.

The HPLC methods employed the columns and methodology described previously. The target analytes were all resolved when eluted from a Supelco LC-18 column (25 cm × 4.6 mm i.d., 5 μm particles) with methanol–water (1 : 1 v/v). These explosives were also eluted and resolved using the same eluent from the "confirmation" column, which was a Supelco LC-CN (25 cm × 4.6 mm, 5 μm particles), but in a nearly inverted order. UV detection at 254 nm was employed, as discussed previously. Weisberg and Ellickson[65] further recommended a complete solvent change to methanol with a 5-min hold to flush the column, followed by a gradual return to the initial program conditions over a 5-min period. This practice elutes nonpolar nontarget analytes that will otherwise elute in subsequent samples and interfere with the usual determination method. The authors observed that the benefits of greater baseline stability outweighed the longer analysis turnaround time.

Overall, the method described above was sufficiently robust and reliable to be approved for both "Official First Action" and "Final Action", first by the AOAC, then by the USEPA (Method 8330, "Determination of Concentration of Nitroaromatics and Nitramines by High-performance Liquid Chromatography"). The MDL[66] and CRL values were calculated for thirteen target compounds, as shown in Table 7. MDL values ranged between 0.03 μg g^{-1} soil for 2,4-DNT and 2-Am-DNT, to 1.27 μg g^{-1} for HMX; however, HMX was the only species where the MDL exceeded 1 μg g^{-1}. Recoveries ranged between 80% (for HMX) to 119% (for TNB).

Table 7 Detection capability estimates and overall analyte recovery for the standard analytical method for munitions in soil

Analyte	MDL[a] ($\mu g\,g^{-1}$)	CRL[b] ($\mu g\,g^{-1}$)	Recovery (%)
HMX	1.27	2.15	80
Tetryl	0.12	0.65	83
RDX	0.74	1.03	84
2-Am-DNT	0.03	0.11	91
O-NT	0.07	0.24	92

4.3 Performance of the Standard United States Environmental Protection Agency Method 8330

Soil samples obtained from two independent EOD sites were analyzed by staff members of the Cold Regions Research and Engineering Laboratory (CRREL) and Missouri River Division Laboratory (MRD). At both sites, 2,4-DNT was detected in all samples with detectable analytes. The 2,4-DNT was present at much higher concentrations than TNT, the reverse of what is found at other types of sites. The source of this contamination was probably the improper demolition of excess propellant (i.e. it was detonated, not burned). In fact, whole propellant grains were found scattered about each EOD site.

GC/MS analysis of acetonitrile extracts of soil samples and propellant grains confirmed the presence of diphenylamine and dibutylphthalate, which, along with nitrocellulose (NC) and 2,4-DNT, are the ingredients of M1 propellant.[3] Most analytes could be confirmed using the cyano (LC-CN) confirmation column eluted with $1.5\,mL\,min^{-1}$ 1:1 methanol–water, as specified in Method 8330. HMX and RDX, which elute several minutes before TNT on the analytical column (LC-18), elute after TNT on the confirmation separation. This dramatic shift in retention order makes the confirmation of nitramines certain. However, confirmation of DNT is difficult in many cases. The isomers of DNT elute close to TNT on the confirmation separation, and since they are often present at much lower concentrations than TNT, their confirmation may be ambiguous. However, some improvement in the resolution of 2,4-DNT and TNT can be achieved using a slower flow rate ($1.2\,mL\,min^{-1}$) and a weaker eluent (35:65 methanol–water). Additionally, this flow rate and eluent greatly improve the separation of 2-Am-DNT and TNT.

Another problem associated with the confirmatory separation for some samples is the presence of many more peaks in the confirmation chromatogram than in the

Table 8 Concentration ranges observed for various explosives in soil and water. Samples analyzed by staff members from CRREL and MRD

Analyte	CRREL[a]		MRD[b]		Median concentration for combined data sets	
	Soil ($\mu g\,g^{-1}$)	Water ($\mu g\,L^{-1}$)	Soil ($\mu g\,g^{-1}$)	Water ($\mu g\,L^{-1}$)	Soil ($\mu g\,g^{-1}$)	Water ($\mu g\,L^{-1}$)
HMX	t[c]-5700	0.13–673	0.13–365	2.45[d]	3.7	76
RDX	t-13 900	0.02–1400	0.19–105	0.1–162	3.6	3.0

analytical chromatogram. The cyano function on the LC-CN ''confirmation'' column is less retentive for aromatic compounds than the hydrocarbon-based phases of the LC-18 or LC-8 ''primary'' analytical columns. Because the confirmation column is less retentive, it is more prone to interference from nontarget analytes that have long retention times on the LC-18.

The concentration ranges observed in this study for various explosives and related products in soils and water ranged from ''nondetectable'' to thousands of parts-per-million in soil or water, as shown in Table 8.

4.4 Additional Procedures

Several new approaches to the extraction and quantitation of explosives in soil have given the analytical chemist more choices for determining these species both rapidly and reliably. For example, ASE™ employs both elevated temperature and pressure to extract a solid sample in a sealed vessel rapidly. A manufacturer's application note[67] describes the rapid extraction (14 min) of small soil samples using either acetone or methanol (17–50 mL sample^{-1}). This approach was tested with clean soil spiked with explosives, authentic contaminated soils from Germany, and heavily contaminated wet soil. For the latter, 2.5 g soil were mixed with 0.8 g diatomaceous earth prior to extraction. In all cases, the recoveries from the ASE™ were greater than those with sonication. Parallel results obtained using Soxhlet extraction were not reported. Extractions from wet heavily contaminated soils were reproducible (6% RSD at 3500 mg TNT kg^{-1}).

Griest et al.[68] described the separation of explosives using packed-column supercritical fluid chromatography (SFC). The eluent employed was SFC-grade carbon dioxide without modifier. The analytes were eluted from microbore Deltabond® Cyano columns (2.50 or 1.50 m × 1 mm i.d.). The instrument employed both a variable-wavelength UV detector (12 μL flowcell) and a flame ionization detector (FID) in series, enabling facile detection of both the nitroaromatic and nitramines. Eight explosives eluted in the order 2,6-DNT < 2,4-DNT < NG < TNT < PETN < tetryl < RDX (some tailing) ≪ HMX (was not observed). The authors postulated that the addition of a polar modifier such as methanol would have allowed HMX to elute from the column and be detected.

Miyares[69] explored the possibilities of SFC further to enable the facile elution of HMX, which was not possible using the conditions described in Griest et al.[68] The author employed short narrow-bore SB-Cyanopropyl columns (2.5 m or 5.0 m × 0.05 mm i.d.). HMX was finally eluted as a clean sharp peak with supercritical fluid grade carbon dioxide using the SB-Cyanopropyl-25 capillary column (5.0 m × 0.05 mm i.d.); however, resolution of the earlier-eluting explosives was sacrificed compared to that observed in Griest et al.[68] Miyares also compared the instrumentation and ease of method development between SFC and HPLC, and noted the following:

- SFC columns are smaller and more flexible than GC columns, and are much harder to install than HPLC columns. HPLC columns may be installed or removed in less than one minute, compared to up to 15 minutes for SFC columns.
- Method development involving reversed-phase HPLC columns is fairly straightforward because retention times are strongly correlated to octanol–water partition coefficients. It becomes reasonably easy for an experienced operator to choose the column phase, mobile phase, and gradient (if required). In SFC, the partitioning of analytes between the mobile and stationary phases is part of the partition mechanism for separation, but it may also include specific effects from density, temperature, linear velocity, and volatility of analytes. The temperature, density, and pressure of supercritical fluids are interrelated in such a way that for a given density, there are many temperature and pressure combinations. Consequently, considerably more trial-and-error is required for SFC method development than for HPLC method development.
- The standard HPLC method employs simple isocratic elution, which may be executed using even very unsophisticated pumping systems. In contrast, the SFC separation reported in Miyares required an intricate combination of temperature and density ramps which demanded a highly sophisticated pumping system.

Taken together, Miyares concluded that for routine environmental monitoring and site characterization required by the military, SFC offered no substantial advantages over the standard HPLC/UV methods.

Rodacy et al.[18] discussed the application of IMS both to aqueous samples, as discussed earlier, and soils. Explosives are desorbed thermally from soil samples prior to introduction into the IMS. Each explosive examined to date, including TNT, RDX, PETN, ethylene glycol dinitrate (EGDN), NG, HMX, and DNT have unique and repeatable delay times for any given temperature up to the point where sample decomposition occurs. The type of soil being analyzed does not affect the relative delay times because explosives desorbed from soils containing high sand content, high clay content, high humic matter, and pure quartz surfaces show the same relative delays. However, if one compares the length of time it takes for an explosive to be desorbed from, say, a sandy soil and a soil with high humic content, a slight difference in desorption times can be noted. The differences, however, are minor

and of no importance to the analysis. This combination of desorption profile with ion mobility allows accurate, unambiguous differentiation of the explosive species and eliminates many potential interferences. A prototype system was developed and used for the analysis of RDX, TNT, DNTs, and PETN in both water and soil samples. The system was challenged with 700–800 soil samples contaminated with explosives ranging in concentration from ''not detected'' to 50–60 ppb. Approximately 10% of these samples were ''split'' and analyzed both ''in house'' using the prototype method and by an independent laboratory using USEPA Method 8330. In all cases, there was excellent agreement between data generated for a given sample by the two procedures.[70]

Interferences to the IMS method found to date are extremely limited, and include such diverse sources as wintergreen-flavored snuff, Brut™ deodorant, some musk perfumes, and some freshly cut foams and fresh adhesive tapes. After having been exposed to the atmosphere for approximately two hours, the foams cannot be detected; after 6 to 12 hours, the tape can no longer be detected. These materials may be possible contaminants, but not interferences, because the drift times and desorption lag time allows unambiguous separation of these materials from the explosives. To date, the authors have not been able to detect true interferences which are native to soils.

In analyzing soil samples, the explosive vapors are detected as they are desorbed. Using a 200 milligram soil sample (optimal for the desorption furnace), the following detection limits were obtained: 0.5 ppb TNT; 3.0 ppb RDX; 0.5 ppb NG; 2.0 ppb PETN; 4.0 ppb EGDN. (The criterion for ''detection limit'' was not specified.)

The IMS shows a linear calibration curve from approximately one to 100 picograms of TNT and RDX. Larger quantities of explosives produce a nonlinear asymptotic response. This falloff could be attributed to one or more of the following phenomena: insufficient reactant ions in the source; space charging; and the increasing likelihood of ion–ion collisions to form neutral species.

At least two authors have noted difficulties in detecting TNT, in particular using a direct thermal-desorption inlet to an IMS, and have reported a much higher detection limit than Rodacy.[18] Some of these discrepancies may be explained by differences in both sample and instrument characteristics, as follows:[71,72]

- Explosives may be detected easily at low concentrations if they are artificially spiked onto a soil sample. The analyte does not have sufficient time to diffuse into the tiny pores on the surface, and is therefore removed easily.
- Explosives may be detected at concentrations exceeding hundreds of ppm (i.e. >0.01%) in authentic contaminated soil, but not at lower levels.
- The sensitivity of the IMS instrument is critically dependent upon the design of the desorption furnace (short vs long heated zones). The transfer line must be heated to avoid any possible cold spots which would promote analyte condensation prior to introduction into the ion source.
- TNT is detected as TNT, rather than as a degradation product.

Jenkins and Walsh[73] extended previously reported work concerning the application of GC/ECD in aqueous samples to include soils. Use of this approach permitted detection limits of about $1\,\mu g\,kg^{-1}$ for the important signature chemicals, without additional preconcentration. This method employs short (6 m) Megabore (0.53 mm i.d.) fused silica columns with deactivated injector liners and linear velocities of about $100\,cm\,s^{-1}$. The authors resolved 20 important nitroaromatic, nitramine, and aminonitroaromatic signature chemicals within a 15-minute analysis time using a 6-m HP-5 column. This method has been given preliminary approval by the USEPA as SW-846 Method 8095.

Yinon et al.[74] described the application of thermal pyrolysis/GC/MS for several explosives, including RDX, HMX, tetryl, monoaminotrinitrobenzene (MATB), diaminotrinitrobenzene (DATB), and triaminotrinitrobenzene (TATB). The final pyrolysis temperature was 400–1000 °C, held for 2 seconds. The nitramines RDX and HMX showed similar mass spectra upon pyrolysis, both of which were very different from those of the three nitroaromatics.

5 DETERMINATION OF EXPLOSIVES USING FIELD SCREENING PROCEDURES

5.1 Introduction and Motivation

The preceding discussions all tacitly assumed that the determination of explosives in either aqueous or soil samples would be performed (a) using standard well-validated methods (b) using highly instrumented analytical methods (c) in a well-equipped laboratory (d) in a timely manner. Such scenarios frequently are not helpful for routine site clean-up operations. ''Traditional'' analytical laboratories are rarely available at a clean-up site. Further, reliable analytical data needs to be available *immediately* so that remediation personnel may make correct and timely decisions. Lengthy delays imply that expensive excavation equipment and skilled operators must remain idle for indefinite periods of time. Crockett et al.[6] described additional complications and considerations as follows:

Reliance on laboratory analyses only for site characterization may result in a large percentage of samples (up to 80%, depending upon the site) with nondetectable levels. The remaining samples may indicate concentrations within a range of four orders of magnitude. Analyzing a small number of samples at an off-site laboratory may result in inadequate site characterization for estimating soil quantities for remediation and may miss potentially reactive material. ... Laboratory analytical costs vary depending on required turnaround time. Typical costs for USEPA Method 8330 range from $250 to $350 per sample for 30-day turnaround, $500 to $600 for 7-day turnaround, and approximately $1000 per sample for 3-day turnaround, if it is available. [Reproduced by permission of the Cold Regions Research and Engineering Laboratory from A.B. Crockett, T.F. Jenkins, H.D. Craig, W.E. Sisk, *Overview of On-Site Analytical Methods for Explosives in Soil*, Special Report 98-4, 3, 1988.]

Taken together, there is an urgent demand for analytical procedures which are:

- well-documented and validated;
- fieldable at clean-up sites;
- easily operated by nonchemical professionals;
- rapid;
- capable of producing valid analytical data quickly;
- inexpensive.

5.2 Description and Evaluation of Typical Colorimetric Field Screening Procedures

Many of the existing and successful analytical field test kits for explosives in environmental samples are based upon two well-documented chemical reactions. As early as 1891, Janowsky[75] observed that colored reaction products were observed when polynitroaromatic compounds reacted with alkali such as potassium hydroxide in the presence of acetone. Meisenheimer[76] and Jackson and Earle[77] independently proposed a final end product with a quinoidal structure to explain this phenomenon. In general, Jackson–Meisenheimer anions for dinitroaromatics are blue to purple in color and those from trinitroaromatics are red.[78] The formation of Jackson–Meisenheimer anions has historically been the basis of a reliable field test for nitroaromatics. The reactions are summarized in Scheme 1.

Colorimetric chemical methods have also been developed for RDX and the nitramines for forensic applications.[79] These procedures generally rely on sequential reactions where zinc metal converts RDX, for example, to nitrous acid (Franchimont reaction). The resulting nitrous acid is used to nitrosate an aniline derivative such as sulfanilic acid; the resulting diazo cation is then coupled to a naphthylamine to form a highly colored azo dye (Griess[80] reaction). This reaction sequence is summarized in Scheme 2. Several pairs of reagents may be

Scheme 1 Reactions used for the colorimetric determination of TNT and DNT. [Reprinted from T.F. Jenkins, M.E. Walsh, *Talanta*, **39**, 420 © 1992 with permission from Elsevier Science.]

used to produce azo dyes. A reagent containing procaine and *N*,*N*-dimethylnaphthylamine was initially used for the procedure described in Jenkins and Walsh.[81] This choice was based on the work of Wyant, who tested several reagents and found this combination best in terms of detection capability and shelf life.[82] However, this liquid reagent is light-sensitive, and therefore cumbersome to handle in the field. In addition, there was some concern about the possible cancer risk associated with *N*,*N*-dimethylnaphthylamine. Further work demonstrated that a Hach NitriVer 3 ''powder pillow'', which is specifically designed for the determination of nitrite in the field, and distilled water, can be substituted for the liquid Griess reagent. The powder pillow contains sodium sulfanilate, 4,5-dihydroxy-2,7-naphthalene-disulfonic acid disodium sulfate, potassium phosphate monobasic, potassium pyrosulfate, and *trans*-1,2-diaminocyclohexane tetra-acetic

acid trisodium salt. Abramovich-Bar et al.[83] described an additional set of workable Griess reactants. Here, a diazonium salt is formed from sulfanilamide and nitrite in the presence of 10% phosphoric acid. This product, in turn, reacted with *n*-naphthylethylenediamine to produce a red azo dye compound.

Jenkins and Walsh[81] described colorimetric field screening procedures (the ''CRREL Methods'') for explosives. Approximately 20 g wet soil is shaken with 100 mL acetone, and the extract filtered with a disposable syringe filter. The first test is designed to detect nitroaromatics. Portions of the extract are reacted with a strong base and sodium sulfite. If only TNT is present, a reddish Janowsky complex is produced. If only DNT is present, a bluish-purple complex is produced. If a mixture is present and TNT dominates, DNT will not be detected. The second test is designed to detect nitramines, primarily RDX. A second portion of acetone extract, which is first passed through a disposable anion exchange cartridge to remove native nitrate or nitrate, is acidified and reacted with powdered zinc. The nitrous acid so produced is reacted with the contents of a Hach NitriVer3 powder pillow and distilled water, as described above. The development of a pink Griess reaction product is indicative of the presence of RDX or one of several other military explosives which are potential interferents (HMX, NG, PETN, or nitrocellulose (NC)). A battery-operated spectrophotometer may be used to quantitate the products so formed at 540 nm (for TNT and nitroaromatics) and 507 nm (for RDX and the nitramines). While absorbance of the Janowsky product is greater at 460 nm than at 540 nm, the latter wavelength was selected to reduce interferences from yellowish humic materials that are also extracted into acetone and absorb strongly at 460 nm.[1] The detection limit was 1 $\mu g\, g^{-1}$ for TNT and RDX, with linear range extending to 50 $\mu g\, g^{-1}$ for TNT and 20 $\mu g\, g^{-1}$ for RDX.

Medary[84] reported a related screening procedure for TNT in which methanol, not acetone, was the extraction solvent. TNT was estimated for the absorbance of the colored Meisenheimer anion produced at 516 nm, and a detection limit of 4–8 $\mu g\, g^{-1}$ is estimated. The major advantages of the procedure described in Jenkins and Walsh[81] include a four-fold greater absorbance of the colored product and better extraction of the nitramines when acetone, not methanol, was employed. The same authors investigated the extraction recovery of the proposed field method by both shaking aliquots of soil manually (3 min) and ultrasonically extracting identical portions for 18 hr with acetone. The average recovery after 3 min of manual shaking with acetone for TNT was 96% and for RDX was 98% of that obtained with the more exhaustive procedure, indicating that acetone is an excellent extraction solvent for these two analytes over a wide concentration range. Subsequent studies indicated that longer extraction times (up to 30 minutes) were useful for soils with a ''heavy'' clay content.

The color-forming reactions used for these field screening methods are not specific for TNT, 2,4-DNT, and RDX. Other polynitroaromatics such as 1,3-DNB and 1,3,5-TNB and polynitrophenols such as picric acid (PA) also give colored anions when reacted with strong base. During site clean-up activities, however, the ability to detect these other compounds, as well as TNT and 2,4-DNT, would be quite useful. Similarly, the same azo dye produced from the RDX test is also produced when other nitramines such as HMX and tetryl or nitrate esters such as NG, PETN and NC are treated under similar conditions. Heavy metal cations such as copper were found to interfere with the 2,4-DNT determinations. These cations could form complexes with either the unreacted DNT or the Janowsky complexes.

Absorbance varied little for the TNT and RDX solutions over the range of moisture contents (10–75%) expected for the large majority of surface soils from potentially contaminated sites. However, the absorbance for the 2,4-DNT standard significantly declined as the water content exceeded 10%. Based on this variability, determinations for 2,4-DNT will be semi-quantitative, while the corresponding procedures for TNT and RDX may be used quantitatively.

The extraction procedure described in Jenkins and Walsh[81] was field-tested extensively with authentic contaminated soil samples. The concentrations obtained in the field for TNT, RDX, and 2,4-DNT were compared with those using USEPA Method 8330, which was described previously. In all cases, there was excellent agreement obtained between the concentrations obtained using the two procedures; the typical recovery using the field procedure exceeded 90%. These data are summarized in Table 9. The success of the colorimetric method for TNT led to its adoption as a standard analytical method, entitled USEPA Method 8515, ''Colorimetric Screening Method for Trinitrotoluene (TNT) in Soil''. The RDX method has also undergone standardization as SW-846 draft method 8510.

5.3 Description of Antibody-based Field Test Kits

Recent alternatives to the classical colorimetric assays for explosives, such as those described above, are field tests employing enzyme-linked immunosorbent assays (ELISA).[85] One such assay for TNT involves several steps. In step 1, the plate is precoated with a TNT-protein conjugate that adheres to the well surface. In step 2, competitive inhibition occurs when samples containing TNT are incubated with mouse anti-TNT antibodies. The antibodies can either bind to the free TNT in the

[c] Value calculated relative to the laboratory procedure.

samples or to the TNT bound to the surface of the well. After an equilibrium is reached, the plate is washed and the antibodies bound to the free TNT are washed away, leaving the antibody bound to the immobilized conjugate. The greater the concentration of TNT in the sample, the less monoclonal antibody is available to the immobilized TNT conjugate. Therefore, the amount of antibody bound to the well is inversely proportional to the TNT concentration present in the sample. In step 3, the plate is incubated with goat anti-mouse (μ-chain specific)-alkaline phosphatase conjugate which bonds only to the surface-bound mouse monoclonal anti-TNT antibodies. The plate is washed again. In step 4 the enzyme substrate is added. The surface-bound enzyme–antibody conjugate converts the colorless substrate to a yellow product. The color is directly proportional to the amount of TNT monoclonal antibody bound in each well, and, therefore, is inversely proportional to the amount of TNT in the sample. Mouse monoclonal anti-TNT antibody for TNT is specific for TNT and shows no cross-reactivity with those explosives or interferent tested in this study. The assay was capable of detecting as little as 50 pg TNT.

Musks, as well as a number of other chemicals, are known to present potential interferences with chemical or instrumental means of explosive detection. For example, synthetic nitro musks are similar in chemical structure to TNT and are common fragrance additives in toiletries. To determine the effects on the assay, 100 μL of 2 undiluted musks perfumes – an extreme quantity – were added directly to the microtiter plates in triplicate. In these cases, some inhibition of color development was observed. This may be due to partial stripping of the coating antigen from the plate or binding to the monoclonal anti-TNT antibody.

Westinghouse's Law Enforcement Products Division has developed an antibody-based method for PETN using a latex-bead agglutination technology.[85] Agglutination reactions are widely used throughout the biochemical community for the detection of small quantities of

proteins and drugs in physiological fluids. The time required to complete a PETN assay was reduced to 30 seconds. The sample collection device and assay are being incorporated into a disposable item which is analyzed using a reusable hand-held spectrophotometer. In step 1 of the assay, agglutinated latex particles form when the latex particles (<1μm particles) which have covalently bound to their surface the analyte of interest, are mixed with the specific antibody. Because of the multiple binding sites on both the latex particles and the antibody, a crosslinking or polymerization of many particles occurs. In the presence of the analyte of interest, this agglutination is inhibited. This agglutination reaction can be monitored both visually and electronically in about 30 seconds. PETN antibodies from one particular rabbit showed detection as low as 30 parts per trillion using an ELISA assay similar to the TNT assay. Recent preliminary results of the agglutination assay have demonstrated a detection limit of 25 ng of PETN.

Bart et al.[86] described a continuous-flow immunosensor (CFI) which would be capable of fulfilling the mission of an explosives detector for both environmental analysis and bomb detection. The CFI is a semi-automated system in which the analyte-containing medium (generally an aqueous sample which is spiked with a concentrated solution of buffer, organic co-solvent, and a surfactant) is pumped through a column containing antibodies immobilized on beads. These antibodies are saturated with a fluorescent analog of the analyte before the analysis begins. As the analyte passes through the antibody matrix, some of the analyte binds to the antibody, displacing the labeled analog. The effluent from the column is thus a mixture of analyte which did not bind to the antibodies and dye-labeled antigen which was displaced by the analyte; the fluorescent analog is then detected in a fluorometer located downstream from the column. The amount of dye-labeled antigen displaced is directly related to the amount of analyte in the sample. A prototype system was assembled and evaluated for the evaluation of RDX in aqueous samples over the range 15–1200 ng RDX mL^{-1}. The lowest detectable limit was 20 ng RDX mL^{-1}. The cross-reactivity of other explosives with the anti-RDX antibody was modest for HMX (15% response vs RDX), and minimal for TNT and its derivatives (typically <1%). This behavior was expected because of the structural similarities of RDX and HMX, and dissimilarities of RDX and TNT. When both the CFI and standard HPLC methods were used to analyze several groundwater samples for RDX, the agreement between the two methods was excellent. Kusterbeck and Charles[87] described the extensive field demonstration of a similar device, the FAST 2000, for the determination of TNT at two Department of Defense Superfund cleanup sites. The procedure was cost-effective and capable of screening a number of samples in a short period of time at a project cost of approximately $3–$10/sample, compared to $250–$1000/sample using the standard HPLC method.

5.4 Evaluation of Commercially Available Field Screening Kits

The frequency of occurrence of specific explosives in soils was assessed using analytical data on soils collected from 44 army ammunition plants, arsenals, and depots, and two EOD sites.[3] Of the 1,155 samples, a total of 319 samples (28%) contained detectable levels of explosives. TNT was detected in 66% of the samples and 80% of the samples if the two EOD sites are excluded. Overall, TNT or RDX or both were detected in 82% of the samples containing explosive residues, and 94% if the ordnance sites are excluded. Thus, by screening for TNT and RDX at these facilities, 94% of the contaminated areas could be identified (80% if only TNT was determined). This demonstrates the feasibility of screening for one or two compounds. Screening for all of the explosives listed in USEPA Method 8330 was not necessary to evaluate the degree of contamination in a particular site.[1,20,88] For that reason, several manufacturers now offer commercially available test kits which focus on the determination of TNT and RDX. These kits have been evaluated extensively by many independent authors, with their performance summarized[6,88,89] in the following general comments:

- A USEPA study[90] compared the CRREL, EnSys (colorimetric), D Tech, Quantix, and Ohmicron methods for TNT. Overall, no single method significantly out-performed other methods, and the accuracies for all the field screening methods were comparable.
- Myers et al.[91] compared the EnSys colorimetric test to a commercial enzyme immunoassay (EIA) procedure that utilizes an immunofiltration approach (D Tech) using 99 soil samples obtained from the NSWC. The results from both methods were compared with analyses conducted using the standard reversed-phase high-performance liquid chromatography (RPHPLC) laboratory procedure (SW-846 Method 8330). Quantitative agreement between the field screening results and the RPHPLC results was somewhat better for the colorimetric method; however, a portion of this advantage may be due to larger sample sizes utilized in the EnSys protocol, which results in reduced sampling error.

- Haas and Simmons[92] evaluated immunoassay kits for TNT (EM Science/D Tech, EnSys/EnviroGard Tube and Plate, Idetek/Quantix, and Ohmicron/RaPID Assay.) They concluded that for semiquantitative screening, all kits have the potential to accurately screen soil samples for contamination at risk-based levels. The correlation between the immunoassay kits and HPLC was generally good above the 1 ppm level.
- A study conducted by the USEPA Region 10[93] and reported in Jenkins et al.[1] compared two versions of the colorimetric test (CRREL[81] and the EnSys commercial version) and two commercial immunoassay methods (D Tech and Quantix) during Phase 1 of the explosives washout lagoon soil remediation project at the Umatilla Army Depot. Samples were also analyzed using RPHPLC Method 8330; these results served as the basis for comparison. Overall, the CRREL colorimetric method was judged the least expensive for large sampling efforts and the most accurate for concentrations above $30\,\mu g\,g^{-1}$, while the D Tech EIA procedure was judged the most accurate below $30\,\mu g\,g^{-1}$. The Quantix method, which utilizes an EIA approach in the plate format, was judged the most efficient method for large numbers of samples. Overall, this study confirmed the value of the use of field screening for explosives-contaminated sites.
- A major field demonstration and evaluation of on-site analytical methods was performed during full-scale remediation at the Umatilla Chemical Depot (Hermiston, OR) and US Naval Submarine Base (Bangor, WA) Superfund sites. An additional evaluation involved pilot scale composting at the NSWC (Crane, IN) RCRA Corrective Action site.[94] Compost samples were analyzed by each of the on-site methods and results compared to standard laboratory analyses employing HPLC. The on-site methods evaluated included EnSys TNT and RDX colorimetric methods (USEPA SW-846 Methods 8515 and 8510) with and without an organic matrix cleanup step, and D Tech TNT and RDX immunoassay methods (USEPA SW-846 Methods 4050 and 4051). This study indicated that both colorimetric and immunoassay methods may be used for determination of explosives concentrations in compost residues during bioremediation treatment.

5.5 Field Test Procedures for Picric Acid and Ammonium Picrate

Ammonium picrate (AP; Explosive D; Yellow D) was used in armor-piercing shells, bombs, and rocket warheads by the US military from the turn of the century until after World War II. Although it is no longer manufactured, AP represents 8% of the demilitarization inventory. Picric acid (PA) was used in grenades and mine fillings. Unlike many of the other high explosives that are no longer manufactured and present environmental clean-up problems unique to the military, PA is a common industrial chemical, used widely for metal etching and as a feedstock in many processes in the dye, leather, and glass industries.[95]

Thorne and Jenkins[95] described the optimization of a field analytical method for AP/PA in considerable detail, with the final procedure sketched as follows: soils are extracted with acetone in a manner similar to the colorimetric screening methods for TNT and RDX. A 30-mL filtered aliquot is mixed with 30 mL of deionized water and passed through a 3-mL SPE-Alumina-A (Supelco) cartridge. Picrate ion is retained on the alumina. Interferences are removed by passing a 3-mL aliquot of methanol through the cartridge, followed by a 3-mL aliquot of acetone. Picrate is converted to PA with a solution of 10 mL acetone containing four drops of sulfuric acid and eluted from the cartridge. The solution is then diluted with 5 mL of deionized water and 15 mL of acetone. A change from the colorless (PA) to yellow (picrate) is indicative of the presence of PA/AP in the soil at a concentration above $3\,\mu g\,g^{-1}$. The picrate concentration can be estimated from the absorbance of the solution at 400 nm with a MDL of $1.3\,\mu g\,g^{-1}$. In the same study, concentrations of picrate were measured in 49 contaminated soil samples using both the field method described and RPHPLC. The results obtained exhibited an excellent correlation over three orders of magnitude. The field method did not produce false positives.

5.6 Field Screening Procedures for Explosives in Soils using Ion Mobility Spectrometry

IMS was evaluated as a potential field screening procedure for explosives in soil.[96] The US Army provided a large number of soil samples that had been collected from three locations at each of three explosive contaminated installations, dried, ground, homogenized, and previously analyzed in duplicate using Method 8330. Duplicate two-gram aliquots of these samples were extracted with 10 mL of acetone by shaking for three minutes. After solids had been allowed to settle, the quantities of ''typical'' explosives were determined using IMS. For field application, the extraction procedure should be changed to 20 g moist soil, 100 mL acetone. The chief limitation of the IMS method was the initial cost of instrumentation ($\sim$\$50 K).

6 TRANSFORMATION AND METABOLISM OF EXPLOSIVES IN THE ENVIRONMENT

6.1 Expected Reaction Pathways

The presence of species such as TNB and the various isomers of poly-amino poly-NT suggest that TNT residues in soil may be transformed by a variety of photochemical and/or microbiological processes. While the transformation pathways of some explosives have been studied in cell cultures, composting systems, and water, little research has been conducted to define what by-products are present in explosives-contaminated soil. Griest et al.[97] have reported the aquatic toxicity of TNT and its metabolites using the *Ceriodaphnia dubia* assay. The same source discussed the mutagenic and genetic activity of the same compounds using the Ames test, Chinese Hamster Ovary (CHO) assay, and the Sister Chromatid Exchange (SCE) assay. Potential transformation products of TNT are numerous. Major et al.[8] outlined the following two major and one minor transformation pathways:

- An *oxidation* pathway, in which the methyl group of TNT is oxidized stepwise to the corresponding alcohol, aldehyde, and acid. The latter is ultimately decarboxylated to form 2,4,6-TNB.
- A *reductive* pathway, in which either the 2- or 4-nitro group of TNT is reduced stepwise to the corresponding hydroxylamine and amine. The reduction of the remaining nitro groups would proceed similarly, ultimately forming a 2,4,6-triaminotoluene (TAT) end product. Many bacteria and fungi are capable of performing this reduction.[39] The reduction only proceeds to the monoamine stage under aerobic conditions, and may occur abiotically.[98] If the medium considered is composted soil, which contains a significant quantity of humic organics, a significant fraction of the reduced TNT products will become covalently bound to the matrix.[99]
- A *condensation* pathway, in which monoamine products from the reductive pathway combine to form a variety of azoxy dimers, such as 2,2′,6,6′-tetranitro-4,4′-azoxytoluene (4,4′-Az) and in trace amounts 4,4′,6,6′-tetranitro-2,2′-azoxytoluene (2,2′-Az).[39]

The transformation of TNT does not necessarily mean a removal of its deleterious characteristics; the primary biotransformation products of TNT, which are the dinitromonoamines 2-Am-DNT and 4-Am-DNT, have also been shown to have toxic and mutagenic effects on certain biological species. The toxicity and mutagenicity of secondary and subsequent biodegradation intermediates of TNT, such as the diaminomononitroamines 2,6-Dam-NT, 2,4-Dam-NT, and the trinitroamine TAT, have yet to be explored. Therefore, simple and accurate methods for the identification and quantitation of TNT and its biotransformation products are needed so that acceptable mass balances can be established during biodegradation.[100]

6.2 Analytical Procedures for the Transformation Products

Several investigators have proposed and evaluated a variety of analytical methods to separate and quantitate these various products. Many of these employ either UV absorbance measurements or manipulation of the sample pH. In a very early work, Glover et al.[101] reported both pK_a values and molar absorptivities for the two monoamine and two diamine isomers (total four compounds). Ahmad and Roberts[100] used an Alltech Alltima RPHPLC column (RPHPLC C_{18}, 25 cm × 2.1 mm i.d., 5 μm particles) with a pH gradient to resolve the analytes. A diode array detector was programmed to allow both dual-wavelength detection (at 210 and 254 nm) and compound characterization (scanning between 200–600 nm). Baseline separation of aminodinitrotoluenes could not be achieved using the method presented, which used a strict reversed-phase column, but could be achieved using either a single mixed-mode column[40] or an LC-CN column in series with an RP C_{18} column.[38] Ahmad and Roberts[100] also studied the separation of the various tetranitroazoxy-toluenes, such as 4,4′-Az and 2,2′-Az. Mobile phases consisting of aqueous buffers adjusted to three different pH values in a gradient with acetonitrile were examined for their efficiency in separating the intermediate compounds and for the minimization of speciation of the ionizable intermediates. Solvent consumption was minimized by the use of a narrow-bore column (2.1 mm i.d.). Liquid chromatography/mass spectrometry (LC/MS) supplemented with a UV detector (214 nm) has been used for detecting both the monoaminodinitrotoluenes and 2,4-Dam-NT in the urine of rats fed TNT and the same analytes plus 2,6-Dam-NT in human TNT workers.[102] TNT and its principal metabolites were studied by direct injection electrospray ionization/mass spectrometry (ESI/MS).[103]

Several investigators have reported procedures in which the transformation products of TNT are analyzed using either GC/ECD or GC/MS, rather than HPLC. For example, Huang et al.[104] described a procedure for quantitating 2,6-Dam-NT in urine. Samples were initially neutralized with sodium bicarbonate, then extracted with toluene which was subsequently dried with anhydrous sodium sulfate. Quantitation of the underivatized analyte was performed using GC/ECD. Mußmann et al.[105] described a special procedure for the diaminonitrotoluenes in which the

pH of an aqueous sample was initially adjusted to 12. After batch extraction with dichloromethane and extract concentration, the analytes were derivatized with heptafluorobutyric anhydride (HFBA) or *N*-methyl-bis(trifluoroacetamide) (MBTFA), then separated and detected using GC/ECD. Schoene et al.[106] observed that derivatizations of the TNT metabolites and transformation products performed with *N*-(*tert*-butyldimethylsilyl)-*N*-methyl-trifluoroacetamide (MTBSTFA) were frequently incomplete. More satisfactory results were obtained when MTBSTFA derivatizations were supplemented with MBTFA, as noted above. Detection and quantitation of the derivatized analytes were performed using a gas chromatograph equipped with either a mass-selective detector (MSD) or atomic emission detector (AED).

6.3 Experimental Evidence for the Three Transformation Pathways

Caton and Griest[40] demonstrated clearly that the microbial transformation of TNT in composting material is strongly time-dependent; products both ''grow in'' and ''die out'' with time. The two monoaminodinitrotoluenes were observed in both the fresh composts and their leachates. The two diaminonitrotoluenes ''grew in'' as the monoaminonitrotoluenes decreased in abundance during the course of composting, and then decreased further as composting continued. Except for one of the azoxy dimers (4,4′-Az) in leachates prepared from soils in the early stages of composting, no other transformation products or reduction/oxidation metabolites of TNT (or HMX and RDX) were observed.

Jenkins and Walsh[2,107] evaluated eleven samples of authentic contaminated soils taken from six independent remediation sites for the presence of TNT transformation products. The concentration of the parent TNT in soil ranged from $1\,\mu g\,g^{-1}$ to $14\,mg\,g^{-1}$. Subsamples were extracted with acetone and analyzed by GC/MS. The most common transformation products were 2-Am-DNT and 4-Am-DNT, the initial microbiological reduction products of TNT. TNB, a photodecomposition product of TNT, was identified in 5 out of the 11 soils. Other transformation products identified in 4 out of the 11 soils were trinitrobenzaldehyde (TNBA), and 3,5-DNA. TNBA, like TNB, is a photodecomposition product of TNT, and converts to TNB by decarbonylation (loss of carbon monoxide from the aldehyde). 3,5-DNA is a microbiological reduction product of TNB. The conversion of 3,5-DNA from TNB in soil is consistent with the formation of 2-Am-DNT and 4-Am-DNT from TNT in soil.[3]

Caton et al.[108] investigated the transformation of explosives by common marine micro-organisms. Cultures of *Vibrio*, *Amphora*, or *Skeltonema* were exposed to carbon-14 labeled or unlabeled TNT or RDX coated on steel plates in micro-aquariums to simulate the leaching and transformations of explosives from unexploded ordnance, and the reactions and partitioning of the explosives were followed using HPLC and liquid scintillation counting. TNT was transformed into the same metabolites as have been observed in the composting studies. The water-soluble mono- and diamino-metabolites of TNT were observed in the aqueous phase, while the sparingly soluble (ca. 1 ppm) azoxydimers preferentially accumulated in the particulate phase. In contrast, RDX did not transform appreciably during the experiment, and it accumulated in the aqueous phase.

Hawari et al.[109] evaluated the biotransformation of TNT in anaerobic sludge supplemented with molasses using a combination of SPME/GC/MS and LC/MS. This work confirmed the existence of the reductive pathway, in which the end product is TAT. Under biotic conditions at pH 7.0, TAT is converted according to the condensation pathway first to azoxy dimers and later to polymers. In contrast, under abiotic conditions at pH 2–3, TAT is converted to stepwise to a variety of hydroxydiamine and dihydroxyamine isomers, ultimately yielding 2,4,6-trihydroxytoluene. The biotransformation of TNT to the various reduction products is very rapid, yielding almost complete disappearance of TNT within three hours. The production of TAT increases monotonically for at least seven hours.

Thorne and Leggett[99] hypothesized that reduced TNT products were covalently bound to matrices containing considerable quantities of organic matter, such as composted soil. They exhaustively extracted samples of this matrix contaminated with TNT under three distinct conditions, viz. (a) acetonitrile (removal of all unbound TNT and its reduction products); (b) 50% aqueous sulfuric acid; and (c) 0.5 M sodium hydroxide followed by concentrated sulfuric acid. The authors noted that after 40 days of composting, very little of the amino and diamino reduction products were released by acid hydrolysis. The acid hydrolysis did degrade the matrix substantially, but did not release additional TNT, even though the analyte is stable under the extraction conditions. When the composted soil samples were subjected to an initial base hydrolysis, the quantities of amino and diamino compounds released were roughly equal to those released by the acid-only hydrolysis. However, the subsequent acid hydrolysis of these base-treated samples released considerably more of the reduction products. The authors postulated that the transformation of TNT to solvent nonextractable reduction products appeared to go through two stages of covalent binding to the compost matrix. In the first stage, a significant percentage of the bonds are hydrolyzable by

acid alone or a combination of base and acid. As composting continues, a second stage occurs in which either the bonds are altered to form different functional groups that are nonhydrolyzable or additional bonds form as the bound transformation products are further reduced. This process may result in the potential for long-term releases of TNT metabolites that might not occur if composting is continued into the second stage of nonhydrolyzable binding.

7 DETECTION OF EXPLOSIVES IN AIR

7.1 The Challenge of Detecting Pure Explosive Vapors in Air

The challenge of detecting explosives in the environment is compounded substantially when the sample matrix is air, rather than soil or groundwater. The equilibrium vapor phase concentration of most explosives at 25 °C ranges between 6 and 18 parts per trillion for RDX and PETN, respectively, to 9.4 and 580 parts-per-billion for TNT and NG, respectively – a range of nearly eight orders of magnitude.[110]

Fetterolf[110] noted that attempts to detect pure explosive vapors, particularly in a forensic setting, often fall short of expectations.

> Consider the scenario of a briefcase containing a small amount of plastic explosive such as C-4 (RDX). A simple calculation, using Boyle's gas laws and the equilibrium vapor pressure of pure explosives at standard temperature and pressure, shows that a standard-sized empty briefcase (10.6 L) would contain only 6.3×10^{-11} g or 5.94×10^{-14} g mL^{-1} RDX vapor. This is, however, the best that one can expect. In reality, the amount of explosive vapor available for analysis is much less. These simple calculations fail to take into account Raoult's Law, which states that the true vapor pressure of the explosive will be reduced because it is a component of a mixture. Another factor to be considered is the kinetics or time dependence associated with vaporization and the absorption of explosives on surfaces. TNT has been shown to vapor deposit on a variety of surfaces. Griffy's kinetic model of explosive vapor concentration estimated that until a monolayer of TNT was deposited on the surrounding walls of a room, the vapor pressure was 6×10^{-4} less than the equilibrium vapor pressure. The practical implication of this result is that explosive detectors which function by collecting air samples are unlikely to be effective unless their sensitivity is orders of magnitude greater than that required to detect equilibrium amounts of the vapor. Finally, the emission rate of explosives from the concealment device must be taken into account. Lucero has estimated that this is approximately 1 nL/min. The emission rate of the explosive is also affected by any barrier material, (e.g. plastic wrap or foil) wrapped around it. [Reproduced by permission of the CRC Press © 1995 from D.D. Fetterolf, 'Detection and Identification of Explosives by Mass Spectrometry' in *Forensic Applications of Mass Spectrometry*, ed. J. Yinon, 240–241, 1995.]

Taken together, the physical limitations of the problem dictate that only the most sensitive analytical detection processes will be capable of detecting explosive compounds in air. Some of these are described in the following sections.

The ability to generate explosive vapors of known concentration is a critical concern for calibrating and testing any device used in the sampling of air for the presence of nearby explosives. For example, the Independent Validation and Verification (IV&V) facility (Explosives Detection Systems, a branch of the Federal Aviation Administration at Idaho National Engineering Laboratory) required pulses of explosive vapors between 1 and 1000 pg in less than 5 seconds with a high degree of accuracy. Furthermore, the mass output had to be varied during a test with only a few minutes between pulses. Davies et al.[111] designed and tested a device which employed a heated coil packed with a support containing the desired explosive. The generator was capable of producing pulses of TNT, RDX, or PETN with well-defined concentrations. A typical vapor generator calibration was performed at a fixed coil temperature and pulse width (5 seconds in this study) with the mass output varied by changing the carrier gas flow rate and/or pulse width. Varying the coil temperature to adjust the vapor generator mass output was not feasible in the IV&V tests because of the lengthy equilibration time required to reach a steady-state saturated vapor concentration.

7.2 Canine Detection of Explosives in Air

The traditional method for detecting explosives in air has been the use of canines trained to recognize the ''scent'' of these compounds. A major advantage of dogs is their mobility, a significant improvement over fixed detector installations, which need only be circumvented by a terrorist placing a bomb or smuggling explosives.[112] The use of canines, while widely practiced, exhibits several major drawbacks and concerns. The greatest of these is that there is no objective unbiased understanding of *exactly* how the dog senses the presence of explosives. Unlike machines, dogs do not come with precise specifications, including detection limit, probability of detection, mean time between failure, etc. Many internal and external factors can affect canine olfaction, including heat stress, toxins, injury, and even disease at pre-symptomatic stages. There's no ''press-to-test'' button for a dog to check if the ''system'' is working effectively – a major disadvantage.[113] In spite of these apparent disadvantages, trained canines may fulfill many of the missions assigned to instruments both

more effectively and at lower cost. A major advantage of dogs is that they actually locate suspicious items; at present, machines can only verify the presence or absence of explosives.

A dog's supposed ''supersensitivity'' is a myth. Rather, the dog's accurate and discriminating detection ability make it invaluable. It has never been demonstrated conclusively exactly what causes a trained dog to respond – and, similarly, what causes a false-positive alarm in a dog. A clear understanding of odor signatures should help explain false-positive responses. People have reported bomb-sniffing dogs ''alerting'' on materials unrelated to explosives. In such a situation, more dogs are brought in to sniff the material. If all the other dogs also alert, one concludes that it might be something which, to the dogs, ''smells'' like explosives. It doesn't mean the dog is wrong. The dog may have detected the odor it was trained to smell, but the ''scent'' may be coming from some other material that has the same odor signature as the target substance. For example, a dog trained to look for explosives based on ammonium nitrate may alert at the ''scent'' of ammonium nitrate in garden fertilizer.

Strobel et al.[112] estimated that there are over 19 000 known explosives compositions worldwide. For that reason, it is impractical to condition a dog to alert correctly for each. Nevertheless, the vast majority of explosives are composed of a relatively small number of chemical compounds or ingredients. For that reason, the Bureau of Alcohol, Tobacco, and Firearms have evaluated a new program in which dogs are trained only with pure explosives.[112] In this way, a trained dog should recognize any formulation containing that particular component.

7.3 Mass Spectrometric Detection of Explosives in Air

There has been a long-standing interest in an instrumental approach for trace explosives detection both as a complement to canine olfaction and as a means for explosives detection in scenarios in which canine olfaction is either impractical or inappropriate. For the detection of explosives vapors, gas-phase ionization techniques are the methods of choice. A variety of such methods has been applied to the analysis and detection of explosives vapors, including electron ionization, CI, field ionization, atmospheric pressure ionization, low-pressure electron capture, and atmospheric sampling glow discharge ionization (ASGDI). In general, ASGDI[114] is a simple and rugged means for ionizing organic species. The response is essentially instantaneous, with very little memory effect arising from analyte species that enter the ionization region. Chemical noise arising from the analyte deposited within the ionization volume, which ordinarily requires extensive and time-consuming cleaning with other sources, poses few problems even after many months of nearly continuous operation.

The analysis of negative ions in the explosives detection application is employed because, unlike most compounds in nature, explosives readily form anions. Several other approaches to explosives vapor detection take advantage of this characteristic, including IMS, atmospheric pressure ionization mass spectrometry, and GC/ECD.

Certain physical properties of the ASGDI in particular make it the ideal mass spectrometric source for the detection of explosives in air:

- It exhibits a simple and rugged design which provides a direct interface between the atmosphere and the vacuum system of the mass spectrometer. The ASGDI has no filaments or discharge needles to replace and can be operated continuously for months without maintenance. Despite rather extensive ion burning, source cleaning is not important. Some of the ion sources have been operated over the course of several years without cleaning and show no loss in performance.
- Its high throughput leads to rapid response and pump-out of analyte and minimized memory effects.

The ion-trap mass spectrometer (ITMS) can accumulate selected ions prior to detection; hence, it has the capability of detecting ultratrace concentrations of explosives in air. McLuckey et al.[115] coupled an ASGDI with an ITMS and challenged the new instrument with air containing low parts-per-billion concentrations of TNT. In order to improve the detection capabilities of the instrument still further, both NICI and tandem mass spectrometry were employed. The signal observed at m/z 227 (negative ion mass spectrum) corresponded to the molecular anion from ca. 100 fg TNT. The instrument described has proved to be capable of detecting organic explosives in air at the parts per 10^{12} (trillion) level.

The sensitivity and selectivity of ion-trap mass spectrometric measurements of explosives can be improved substantially by including a filtered noise field (FNF) as part of the ion collection process. FNF is a form of mass-selective ejection, in which undesired masses are removed from the mass spectrometer, and the desired masses are retained, collected, and amplified. When a FNF is applied during ion accumulation, interferences in the desired mass spectra are reduced significantly, and the desired ions, defined by frequency ''notches'', stand out very clearly and cleanly.[116,117] In FNF, a basic waveform having evenly spaced (typically 250, 500, or 1000 Hz) frequency components spanning the frequency spectrum of the entire ion-trap mass/charge range is synthesized digitally. Subsequent digital processing permits the waveform to be shaped so as to effect mass-selective accumulation

(via mass-selective ejection). Moreover, the user can optimize the FNF signal characteristics interactively. Two literature examples illustrate the power of FNF technology: (a) the clean determination of TNT, RDX, and PETN in air at sub parts-per-billion concentrations;[114] and (b) the determination of TNT and the polysulfur ion clusters (S_2•), (S_3•), and (S_4•) in black powder.[116] McLuckey et al.[118] have also applied random noise intentionally to the end caps of an ion-trap as a means of improving the overall selectivity of the device.

Fetterolf[119] discussed the application of IMS to the detection of explosives in air; previous sections in this chapter have described its application to water and soil matrices. In general, IMS possesses many of the desirable analytical figures of merit of conventional laboratory-based instruments such as good sensitivity, selectivity, and speed of analysis. They are often small and simple to operate. This ease of use and portability permit operation in real world scenarios not only as a forensic tool but also as an investigative tool. The Barringer IONSCAN Model 200 was evaluated as a ''typical'' IMS instrument. In the reaction region, atmospheric pressure carrier gas (purified air), hexachloroethane (C_2Cl_6), the reactant gas, and 4-nitrobenzonitrile, an internal calibrant are ionized by a ^{63}Ni beta emitter to form Cl-ions. The use of modified ion chemistry to improve the sensitivity and selectivity of the detection by IMS is quite common. The reactant ions can then undergo one or more ion/molecule reactions with an explosive molecule. In general, negative ionization provides a high degree of selectivity, as discussed earlier. The formation of multiple species greatly increases the specificity and reduces the possibility of false positives since the peak detection algorithm must recognize two of the three peaks for RDX, PETN, and NG before the audible alarm will sound. In one set of experiments, a subject deliberately touched C-4, an RDX-containing explosive, then subsequently touched various parts of an automobile. Samples were collected before and after the contact transfer from each of the touched areas of the car and from the subject's hands by vacuum onto a Teflon® filter disk. An alternative sampling method which has also proven successful is to simply wipe the suspected surface with the sample collector. Careful procedures were followed to ensure that no cross-contamination occurred by verifying that both the sample disks and the IMS were clear of explosives before sample collection. The car surfaces and hands were negative for RDX prior to touching the explosive, but showed easily detectable RDX residue after contact with C-4. In a separate experiment, after handling C-4, eight consecutive hand washes with soap and water were required before the IMS could no longer detect the RDX. Experiments involving the IMS frequently demonstrate presence or absence of a given explosive rather than providing quantitative information. Fetterolf[110] has reported the detection limits (criterion not specified) for TNT, RDX, PETN, and NG as 200, 200, 80, and 50 pg, respectively for at least one of the ions formed in the IMS.

Gieray et al.[120] and Reilly et al.[121] have reported a mass spectrometric method capable of characterizing individual airborne particulates of uranium oxide or diesel engine smoke. The same system was evaluated for real-time mass spectrometry of individual airborne and waterborne explosives particles.[122] Samples of TNT, RDX, and PETN were analyzed on individual particles generated from suspensions of micrometer-sized particles in water, or from solution in acetone. Suspensions and solutions were nebulized and the resulting droplets dried and introduced into the ITMS. When individual particles arrived at the center of the ion-trap, a focused XeCl (308 nm) or ArF (193 nm) laser was used to both ablate and ionize material from the particle. Once the particulate matter was ionized, it was analyzed using a variety of ion-trap-based mass spectrometric methods. Negative ion mass measurements of the three explosives clearly show that acetone, but not water, is involved in the observed spectra obtained using the XeCl excimer laser. Furthermore, PETN particles apparently decomposed when ablated by the XeCl laser pulses, yielding mostly nitrate ions at m/z 62. PETN was also studied with an ArF laser at 193 nm, where the analyte absorbs strongly with little absorption at 308 nm. The work demonstrated that it was possible to generate mass spectra of individual micrometer-sized particles of TNT, RDX, and PETN, either as aqueous suspensions, as dry airborne particles, or as particles nebulized from solution. Preliminary estimates of method sensitivity were not presented.

7.4 Additional Procedures for Explosives in Air

Jenkins and Walsh[73] discussed the determination of explosives in air using SPME fibers as collection devices. Polydimethylsiloxane/divinylbenzene fibers were particularly efficient at collecting vapors of the isomers of DNT, DNB, and TNT. The use of this technique, combined with GC using a new micro ECD, has resulted in the ability to detect many of these energetic chemicals below 1 picogram, with concentration detection limits as low as 10^{-14} g mL^{-1} of air.

8 ADDITIONAL PROCEDURES FOR THE DETERMINATION OF EXPLOSIVES

The procedures which have been discussed in this chapter have been developed using bona fide environmental

matrices, viz. air, groundwater, soil, and compost. A large body of literature exists which describes the detection of explosives in solutions or unusual samples such as hand swabs used in forensics analysis. Some of these procedures will be mentioned here to indicate additional analytical tools available for detecting these compounds in the environment.

8.1 Procedures Featuring Chemiluminescent Nitrogen Detection of Explosives

The use of CLND for the gas- or liquid-chromatographic detection of explosives was mentioned earlier. (For many years, the only CLND device available was the ''TEA'', a product of Thermo Electron Corp. For this reason, the two acronyms are frequently, but inaccurately, used synonymously.) Several investigators have expressed a preference for the ECD because of the latter's greater sensitivity. The CLND exhibits greater selectivity towards nitro-containing compounds and is more tolerant of matrix interferences than the ECD. For that reason, the degree of extract cleanup required is frequently reduced. The explanation for both of these features lies in the three-step operating mechanism of the CLND: (a) combustion of the analyte at 900–1100 °C to form NO, carbon dioxide, water, and other oxides; (b) reaction of NO with ozone to form ''excited state'' NO_2^*; and (c) relaxation of NO_2^* back to ground state NO_2 with the emission of a photon of light in the near-infrared.[123] In general, GC of explosives requires short (typically 6 to 12 m)[124] narrow-bore (250 μm diameter) columns, compared to more commonly used dimensions of 30 to 60 m and 320 to 530 μm, respectively. Thin films are preferred to reduce peak broadening caused by low diffusion velocities.[125] The TEA must be operated in its ''total nitrogen'' mode, in which the furnace temperature is frequently 900 to 1000 °C, to combust the analytes and convert all nitrogen present to nitrogen oxides.[126–129] The dead volume of the TEA or CLND is typically greater than that of a contemporary ECD; hence, some additional peak broadening should be expected when the chemiluminescence detectors are employed.

Douse[130] described the characteristics of a capillary supercritical fluid chromatograph equipped with a CLND. The analytes were eluted through a short nonpolar column (6.8 m × 0.05 mm i.d. SB Octyl 50 Superbond cross-linked flexible silica capillary, 0.25 μm film thickness) with supercritical carbon dioxide (no modifier). Minimum detectable levels (not defined) ranged from 20 to 60 pg for a representative group of compounds: NG (23 pg); PETN (40 pg); tetryl (60 pg); HNBB, hexanitrobibenzyl (55 pg). Compounds containing very polar functional groups, e.g. amino (polynitrodiphenylamines and nitroguanidine) and hydroxy (PA, styphnic acid, and NC) could not be analyzed. In addition, HMX exhibited poor peak shape, probably due to its low solubility in supercritical carbon dioxide. The use of organic modifiers or a more polar supercritical fluid might improve the chromatographic analyses of these compounds. The author noted that some explosives which cannot be analyzed by capillary GC, due to their involatility or instability, were readily analysed by capillary SFC. In addition, capillary SFC/TEA appeared to be more resistant than capillary GC/TEA to contamination by coextractives.

Kolla et al.[131] also noted that the efficiency of SFE, which may be used to extract explosives from soils and related samples, depends not only upon the chemical nature of the analyte but also on the nature of the supporting surface. The influence of the matrix was studied by spiking soils of different carbon content with PETN and NG. The recovery of NG drops steeply if it is mixed into soil of a high carbon content. The recovery of PETN is less influenced than NG by the carbon content of the matrix. If soils with a high humus content are tested, higher pressures and longer extraction times than usual are recommended. As the polarity of the explosive analyte decreases, its retention time from reversed-phase columns increases and its recovery rate in SFE improves. This effect is explained by the increased solubility of nonpolar explosives in the nonpolar supercritical carbon dioxide medium.

In a very recent paper, Bailey et al.[132] described the separation of explosives using capillary electrochromatography (CEC). This can be viewed as a hybrid technique between HPLC and capillary electrophoresis. In CEC, neutral species are separated on the basis of differential partitioning between the mobile and stationary phases, while charged species are additionally separated according to differences in electrophoretic mobility. Under isocratic conditions, using capillaries packed with ~20 cm of 1.5 μm nonporous octyldecylsilica particles and moderate electric fields ($<1000\ V\ cm^{-1}$), baseline separations of all 14 of the Method 8330 components were achieved in under 7 min. Using shorter columns and stronger fields, 13 of the 14 components were separated in less than 2 min. These analysis times represent major improvements in turnaround time compared to the traditional HPLC methods, which typically require 30 min per determination or more. The addition of modifiers such as sodium dodecyl sulfate and/or 2-(*N*-morpholino)ethanesulfonic acid monohydrate reduced tailing in the analyte peaks.

8.2 Procedures Featuring Mass Spectrometric Detection of Explosives

The reason for the outstanding sensitivity of the ECD towards certain explosives is the electron-capturing

nitro groups (up to four) on a given analyte. These same electron-capturing properties also make explosives amenable to highly-sensitive and selective mass spectrometric detection featuring NICI, which can permit greater selectivity and sensitivity than the more traditional and general EI ionization. The mass spectrometer in a given ionization mode is usually coupled with a gas, liquid, or supercritical fluid chromatograph both to separate co-extracted interferences from the analytes and to improve resolution of the explosives from each other and matrix components.

Mass spectra were obtained for several explosives (TNT, tetryl, NG, PETN, RDX) using ''direct exposure CI mass spectrometry'', a form of NICI, with isobutane as the reagent gas.[133] Similar data appears for TNT, NG, PETN, RDX, and HMX using NICI with isobutane as the reagent gas in two additional references.[134,135] A detailed discussion of the EI and CI spectra of explosives is given elsewhere.[136,137]

Huang et al.[104] discussed the application of SFC and Mass Spectroscopy (MS) to the determination of explosives. The application of SFC/MS under EI conditions has been reported; however, it is more difficult to achieve EI conditions in an SFC/MS, compared to a GC/MS, system. CI, therefore, is the most common ionization method for SFC/MS. Methane, ammonia, isobutane, and the supercritical mobile phase itself frequently have been used as the primary reagent gases to generate positive-ion CI mass spectra. The columns employed are frequently short (3 and 6 m), narrow bore (50 and 25 μm internal diameters), with a thin film (0.25 μm thickness 25% biphenyl polysiloxane or SE-54 stationary phases). The supercritical mobile phase evaluated was carbon dioxide doped with either methane or ammonia. Four nitroaromatics, viz. 2,6-DNT, 2,4-DNT, TNT, and TNB were evaluated; the molecular ion was the most abundant for all of them except TNT. No further information about sensitivity or selectivity was provided.

HPLC is frequently preferred to GC as a sample injection method for the mass spectrometer because thermal transformation of the analyte prior to ionization is minimized or eliminated. Typical mobile phases for explosives such as TNT, RDX, PETN, tetryl, NG, and diethylene glycol dinitrate (DEGN) are acetonitrile or methanol–water (50 : 50 v/v).[138] For example, Yinon and Laschever[139] determined explosives in water using direct injection CI with water as the reagent gas. The detection limits (typical signal-to-noise ratio = 5) for six representative explosives ranged between 2 (p-NT) and 40 (RDX, tetryl) ng μL injected. A thermospray (TSP) LC/MS system has been used for the separation and identification of a series of standard and technical explosive mixtures, using positive and negative ion detection, with and without filament CI. The TSP interface appears to offer the greatest capability for analyzing explosives separated by HPLC with high sensitivity. The interface allows high flow-rates (near 2.0 mL min^{-1}) of aqueous solvents and volatile buffers into the system and provides the gentle ionization necessary to obtain molecular ions. The system was tested with individual compounds (TNT, RDX, HMX, PETN, and ammonium nitrate), a technical mixture of RDX/PETN, and a mixture containing TNT, NG, PA, ammonium nitrate, and 2,4-DNT.[140] Positive-ion chromatograms showed only RDX, HMX, and tetryl; PETN, AP, and TNT were not amenable to TSP ionization in the positive mode. On the other hand, when the instrument was operated in the NICI mode, all six components of the standard mixture were readily detected. Detection limits observed in the NICI mode were 200 pg (TNT), 1 ng (RDX, HMX, PETN), 5 ng (tetryl), and 50 ng (AP).

ESI (electrospray ionization) is a sample introduction procedure for HPLC which produces charged droplets in the ion source capable of ionizing species such as explosives. Yinon et al.[141] used such a system in the study of TNT, RDX, HMX, tetryl, PETN, NG, EGDN, and Semtex. The test compounds were eluted isocratically from a short minibore column (Keystone ODS Hypersil column, 15 cm × 2 mm i.d., 3 μm particle size) with either methanol–water (1 : 1) or acetonitrile–water (70 : 30) at 150 or 200 μL min^{-1}, respectively. Mass spectra were obtained in the NICI mode using a Finnigan LCQ ITMS. Standard solutions containing TNT, tetryl, RDX, HMX, and PETN were prepared, and aliquots were injected into the HPLC/MS system. The resulting responses were used to calculate the LODs. The mass spectrometer was operated in the selected ion monitoring (SIM) mode, using characteristic ion or ions for each compound, to provide enhanced sensitivity. The criterion for estimating the LODs was the smallest amount injected that yielded a signal-to-noise ratio greater than 3 for the mass chromatogram of the characteristic ions. LODs were found to be between 5 to 10 pg, corresponding to 1–2 ng mL^{-1} in solution.

Tamiri and Zitrin[142] employed short thin-film fused silica capillary columns in their measurement methods, which featured mass spectroscopic detection using both EI and CI (reagent gas methane). NG, 2,4-DNT, TNT, PETN, RDX, and tetryl emerged as well-resolved peaks. PETN and RDX occasionally failed to elute from longer (30 m) columns; hence, the shorter 15 m columns were preferred. Tetryl routinely degraded partially in the ion source to the stable well-characterized product *N*-methylpicramide, which was frequently used to confirm the presence of tetryl.

8.3 Procedures Featuring Nontraditional Analytical Methods

Some of the most promising new analytical methodologies for detecting explosives in environmental or forensic materials are various magnetic resonance methods which are still in their infancy. For example, hydrogen transient nuclear magnetic resonance[143] (HTNMR) has been found to be particularly useful for the practical detection of most explosives concealed in letters, parcels and baggage. The technique might therefore be applicable for soils. Explosives exhibit HTNMR signal relaxation properties that are different from most other common materials. This feature is absolutely essential to the successful application of this method for inspection since the vast majority of nonmetallic materials contain hydrogen and produce strong hydrogen nuclear magnetic resonance (NMR) signals. Additionally, selectivity is provided in HTNMR by the ^{1}H-NMR to ^{14}N-nuclear quadrupole resonance (NQR) level crossing effect. This provides useful selective signature data for some explosives and is also effective in drastically reducing the analysis time. The unique HTNMR signal relaxation properties have been found to be characteristic for almost all explosives of concern. This includes the high-energy military explosives as well as the more common commercial explosives such as dynamites and water gels used in civilian construction, excavation, and mining activities. Detection is accomplished through magnetic and electromagnetic fields used to sense the hydrogen contained within the materials of the item to be inspected. By analysis and processing of this total hydrogen NMR signal, any contribution to the response produced by hydrogen in explosives can be separated from that produced by the hydrogen in most other materials. Through this procedure the HTNMR response has been found to be useful for rapidly and selectively detecting NG-based dynamites, water gel explosives, C-4 (plastic explosives), RDX, TNT, PETN, smokeless powder, and most other high-energy and commercial explosives and propellants. Results of several thousand tests have demonstrated the general suitability of the HTNMR method for baggage, letter mail, and parcel inspection and have shown a high detection probability and a low rate of false alarms.

Buess et al.[144] discussed the application of ^{14}N pure NQR to the detection of RDX in various samples. RDX was an ideal target compound because it is not only an ideal NQR model compound, but it is also widely used in military applications. NQR is a particularly attractive approach to the problem of explosives detection, because the ^{14}N NQR absorption frequencies from crystalline materials are virtually unique. Hence, by looking for the nitrogen signal at, for example, the NQR frequency of RDX, only those nitrogens in RDX will be detected. Therefore, interferences are not expected with an NQR explosives detector. A literature search of the 10 000 compounds that have been examined by NQR failed to show any other NQR resonances sufficiently near to those of RDX that would constitute a plausible interference. This specificity feature should be contrasted with nuclear-based techniques, for which all nitrogen cross-sections are the same, independent of the chemical composition of the material. Subsequently, NQR would determine the presence of other classes of explosives, (e.g. PETN) by examination at the corresponding NQR frequency for PETN. In principle, such examination could be performed essentially simultaneously with the RDX inspection. NQR is the examination of nuclei with nuclear quadrupolar moments in the absence of a static magnetic field. Hence, in addition to its specificity, a second advantage of NQR is that no magnet is required, in contrast to NMR methods. For that reason, potential damage to magnetically recorded material is avoided; there is no exposure of large, static magnetic fields to personnel. Because a magnet is not required, the costs are lower than for an NMR system. Furthermore, NQR uses nonionizing radiofrequency (rf) radiation, whereas nuclear techniques employ ionizing radiation. There are some inherently unattractive features of NQR which must be addressed before an NQR explosives detector can be marketed commercially. For example, NQR signals are weak and are generally below the level determined by the random electrical noise in the rf coil which detects the signal. The signal-to-noise ratio is increased by repeating the experiment as rapidly as possible and adding up the results; the signal-to-noise ratio improves by the square root of the number of repetitions.

9 SUMMARY AND CONCLUSIONS

The interest in analytical procedures for explosives residues in environmental media steadily increases as more and more formerly utilized military sites are certified and converted to full- or part-time civilian use. Careful statistical studies have clearly demonstrated that analyses based on randomly-collected ''grab'' samples of soils frequently produce a false picture of the extent of explosives contamination. Well-designed sampling plans, which employ multiple samples taken from small areas and which consider the distribution of the soil particles, are mandatory for understanding the true extent of contamination. Because site remediation is such a costly venture, there is a strong need for analytical procedures which are capable of quantitating explosives

in soil and groundwater samples quickly and accurately, using equipment and methods which may be operated reliably by nontechnical personnel. For that reason, scientific interest is gradually moving away from the completely laboratory-based, statistically validated, and highly technical standardized methods, such as HPLC and GC and their mass spectroscopic analogs, towards the many fieldable analytical techniques. Some of these, such as ion mobility spectrometry and the various magnetic resonance techniques, are still in their infancy; their potential and utility are still to be fully developed. Others, such as the colorimetric and enzyme-based field test kits, have been fully tested and, in some cases, have been adopted as standard methods themselves. Still others, such as the various mass spectrometric methods, involve highly technical equipment which must be simplified before it can be used routinely in the field. However, the extreme sensitivities characteristic of these state-of-the-art instruments partially offset the need for extensive operator training. A variety of mass spectrometric techniques may yet be used routinely for explosives residue analysis in the field. Some of these new methods may be used in, or even be derived from, forensic applications.

ACKNOWLEDGMENTS

The author gratefully acknowledges the assistance and suggestions of Dr. Wayne H. Griest (Chemical and Analytical Sciences Division) and Drs. Sylvia S. Talmage and Annetta P. Watson (Life Sciences Division), all of the Oak Ridge National Laboratory, during the preparation of this manuscript. The author also acknowledges Dr. Thomas F. Jenkins, US Army CRREL, for kindly providing many of the CRREL documents which were cited in this chapter. Research was sponsored by the US Army's Rocky Mountain Arsenal pursuant to an Interagency Agreement with the US Department of Energy (DOE), DOE No. 1989-H077-A1. This article was prepared by Lockheed Martin Energy Research Corporation as the Management and Operating Contractor for DOE's Oak Ridge National Laboratory, under federal contract no. DE-AC05-96OR22464.

Reference herein to any specific commercial product, process, or service by trade name, trademark, manufacturer, or otherwise does not necessarily constitute or imply its endorsement, recommendation, or favoring by the United States Government or any agency thereof, or Lockheed Martin Energy Research Corporation. LIST OF SYMBOLS

H_c	Henry's Law Constant
K_{ow}	Octanol–water partition coefficient
X	Mean blank signal
σ	Standard deviation of the blank signal

ABBREVIATIONS AND ACRONYMS

AED	Atomic Emission Detector
AOAC	Association of Official Analytical Chemists
AP	Ammonium 2,4,6-trinitrophenoxide
ASE	Accelerated Solvent Extraction
ASGDI	Atmospheric Sampling Glow Discharge Ionization
ASTM	American Society for Testing and Materials
CEC	Capillary Electrochromatography
CFI	Continuous-flow Immunosensor
CHO	Chinese Hamster Ovary
CI	Chemical Ionization
CLND	Chemiluminescent Nitrogen Detector
CRL	Certified Reporting Limits
CRREL	Cold Regions Research and Engineering Laboratory
DATB	Diaminotrinitrobenzene
DEGN	Diethylene Glycol Dinitrate
DNB	Dinitrobenzene
DNT	Dinitrotoluene
ECD	Electron Capture Detector
EGDN	Ethylene Glycol Dinitrate
EI	Electron Impact
EIA	Enzyme Immunoassay
ELISA	Enzyme-linked Immunosorbent Assays
EOD	Explosive Ordnance Disposal
ESE	Environmental Science and Engineering, Inc.
ESI	Electrospray Ionization
ESI/MS	Electrospray Ionization/Mass Spectrometry
FID	Flame Ionization Detector
FNF	Filtered Noise Field
GC	Gas Chromatography
GC/ECD	Gas Chromatography Electron Capture Detection
GC/ITMS	Gas Chromatography/Ion-trap Mass Spectroscopy
GC/MS	Gas Chromatography/Mass Spectrometry
HFBA	Heptafluorobutyric Anhydride
HMX	Octahydro-1,3,5,7-tetranitro-1,3,5,7-tetrazocine

HNBB	Hexanitrobibenzyl
HPLC	High-pressure Liquid Chromatography
HTNMR	Hydrogen Transient Nuclear Magnetic Resonance
IMS	Ion Mobility Spectrometer
ITMS	Ion-trap Mass Spectrometer
IV&V	Independent Validation and Verification
LC	Liquid Chromatography
LC/ELCD	Liquid Chromatography/ Electrochemical Detectors
LC/MS	Liquid Chromatography/Mass Spectrometry
LOD	Limit of Detection
LOQ	Limit of Quantitation
MATB	Monoaminotrinitrobenzene
MBTFA	*N*-Methyl-bis(trifluoroacetamide)
MDL	Method Detection Limit
MHT	Maximum Holding Times
MRD	Missouri River Division Laboratory
MS	Mass Spectroscopy
MSD	Mass-selective Detector
MTBSTFA	*N*-(*tert*-butyldimethylsilyl)-*N*-methyl-trifluoroacetamide
NB	Nitrobenzene
NC	Nitrocellulose
NG	Nitroglycerine
NICI	Negative Ion Chemical Ionization
NMR	Nuclear Magnetic Resonance
NQR	Nuclear Quadrupole Resonance
NSWC	Naval Surface Warfare Center
NT	Nitrotoluene
OB/OD	Open Burn/Open Detonation
PA	2,4,6-Trinitrophenol
PDMS	Poly(dimethylsiloxane)
PETN	Pentaerythritol Tetranitrate
PICI	Positive-ion Chemical Ionization
RCRA	Resource Conservation and Recovery Act
RDX	Hexahydro-1,3,5-trinitro-1,3,5-triazine
READ	Reversal Electron Attachment Detection
rf	Radiofrequency
RPHPLC	Reversed-phase High-performance Liquid Chromatography
RSD	Relative Standard Deviation
SCE	Sister Chromatid Exchange
SDB-RPS	Styrene–Divinylbenzene 'Reverse-phase Sulfonated'
SEX	1-Acetyloctahydro-3,5,7-trinitro-1,3,5,7-tetrazocine
SFC	Supercritical Fluid Chromatography
SFE	Supercritical Fluid Extraction
SIM	Selected Ion Monitoring
SOE	Salting-out Extraction
SPE	Solid-phase Extraction
SPME	Solid-phase Microextraction
TAT	2,4,6-Triaminotoluene
TATB	Triaminotrinitrobenzene
TAX	1-Acetylhexahydro-3,5-dinitro-1,3,5-triazine
TEA	Thermal Energy Analyzer
tetryl	Methyl-2,4,6-trinitrophenyl Nitramine
TNB	Trinitrobenzene
TNBA	Trinitrobenzaldehyde
TNT	Trinitrotoluene
TSP	Thermospray
USEPA	United States Environmental Protection Agency
UV	Ultraviolet
2-Am-DNT	2-Amino-4,6-dinitrotoluene
2,2′-Az	4,4′,6,6′-Tetranitro-2,2′-azoxytoluene
2,4-Dam-NT	2,4-Diamino-6-nitrotoluene
2,6-Dam-NT	2,6-Diamino-4-nitrotoluene
3,5-DNA	3,5-Dinitroaniline
4-Am-DNT	4-Amino-2,6-dinitrotoluene
4,4′-Az	2,2′,6,6′-Tetranitro-4,4′-azoxytoluene

Atomic absorption spectrometry (AAS) is one of the most often used techniques for the quantitative determination of elements in environmental materials at trace and ultratrace levels. AAS is an optical atomic spectrometric technique based on the measurement of the specific absorption originating from free nonionized atoms in the gas phase. To transfer the analyte to free atoms, different types of atomizer are in use, the flame and the graphite furnace types being the most often used. Typical detection limits of flame atomic absorption spectrometry (FAAS) are of the order of 1–100 μg L^{-1}, making it a perfect tool for the determination of minor and trace elements, at least for contaminated samples. Graphite furnace atomic absorption spectrometry (GFAAS), offering detection limits which are about a factor of 20–200 lower than for FAAS, is the standard method for many trace elements, especially for background values, and for unpolluted samples, such as fresh water and biological materials. AAS in its conventional configuration is a single-element technique, which has to be used in a sequential mode when more than one element has to be determined. However, there are commercial instruments available that can be used for the determination of 6–8 elements simultaneously.

1 INTRODUCTION

AAS is one of the most often used techniques for the quantitative determination of elements (up to 60–70 analytes) in environmental materials at trace and ultratrace levels down to nanograms (ng, 10^{-9} g) and picograms (pg, 10^{-12} g). It is a very well established, reliable and cost-effective analytical tool in thousands of laboratories throughout the world. Its high degree of maturity is reflected in the declining interest of researchers in fundamental research devoted to AAS on one side, while on the other maintaining intensive application of this technique in various areas of analytical chemistry, which is traceable through about 1000 publications per year.

AAS is an optical atomic spectrometric technique based on the measurement of the specific absorption originating from free nonionized atoms in the gas phase. To transfer the analyte to free atoms and provide the hostile environment for these atoms at least for a short moment, different types of atomizer are in use. A scheme of the principle components of an AAS instrument is given in Figure 1.

In FAAS, flames with different fuel–oxidant combinations are used for atomization, whereas in electrothermal atomic absorption spectrometry (ETAAS) different types of electrothermal atomizers are used, such as the graphite tube furnace in GFAAS or the quartz tube atomizer (QTA) in hydride generation atomic absorption spectrometry (HGAAS). These atomizers are meant to provide just the necessary energy via a chain of reactions to transfer the sample into atoms. Most of these atoms are in their electronic ground state with energy, E_0, and are able to absorb energy ($\Delta E = E_1 - E_0 = h\nu = hc/\lambda$) from a radiation source (lamp), where E_1 is the energy of the (first) excited state, h is Planck's constant, c is the velocity of light and ν and λ are the frequency and the wavelength of the atomic spectral line, respectively. The probing beam from the radiation source passes through the observation volume of the atomizer, wherein the radiation is absorbed by the cloud of atoms, which are

Figure 1 Schematic view of atomic absorption (AA) spectrometric techniques. CVAAS, cold vapor atomic absorption spectrometry.

excited to one of their permitted upper energy levels (E_1, E_2, etc.). According to Beer's law, the radiation absorbed is proportional to the number of absorbers in the absorption volume. The ratio of the incident radiant power, I_0, and the power transmitted through the absorption volume, I, is then determined by the detection system of the spectrometer and processed to yield the analyte signal, absorbance, A [Equations 1 and 2]:

$$A = \log_{10} \frac{I_0}{I} = -\log_{10} T \qquad (1)$$

$$A = abc \qquad \text{(Beer's law)} \qquad (2)$$

where T is the transmittance, a is the absorptivity, b is the thickness of the absorption volume and c is the concentration of the absorbing analyte atoms. The relationship between the concentration of the analyte in the sample, c_{sample} and the concentration of the analyte in the absorption volume, c, is normally established via a calibration graph [Equation 3]:

$$c_{\text{sample}} = f(A) \qquad (3)$$

The very high selectivity of AAS originates from the simplicity of the absorption spectra, where only a limited number of lines limits the chance of cases of spectral interference, and the use of line sources that emit just the radiation specific to the analyte, such as the hollow-cathode lamp (HCL) or the electrodeless discharge lamp (EDL). Multielement HCLs are available, but should be used with care, because of the reduction in selectivity due to the possibility of spectral interferences.

The role of the spectrometer in this configuration is limited to the separation of the analytical line from other lines emitted by the radiation source and from emission originating from other sources than the lamp, e.g. the atomizer itself and from emitting species inside the absorption volume. For this reason, the radiation of the lamp is modulated electronically or mechanically with a certain frequency of 50–300 Hz and the detection system is synchronized with this modulation. In order to distinguish the specific AA from other nonspecific absorption due to, for example, molecular absorption or scattering, the AA spectrometer in general uses a background correction system. Commercial instruments are equipped with at least one of the following systems: (a) deuterium background corrector, (b) halogen lamp background corrector, (c) Smith–Hieftje background corrector or (d) Zeeman-effect background corrector, the last one being the most accurate and powerful technique.[1]

2 ATOMIC ABSORPTION TECHNIQUES AND THEIR CAPABILITIES FOR ENVIRONMENTAL ANALYSIS

2.1 Flame Atomic Absorption Spectrometry

Flames with different fuel–oxidant combinations are used for atomization in FAAS, the air–acetylene and the nitrous oxide–acetylene flames being the most popular. The air–acetylene flame generates a flame temperature of about 2525 K, is transparent over a wide spectral range and only starts to absorb radiation below 230 nm. Also, the emission of the air–acetylene flame is very low, so ideal conditions are given for most elements. Normally, this flame is operated stoichiometrically or slightly oxidizing, but it can be operated also in a reducing mode. However, in the reducing mode the lower partial pressure of oxygen is responsible for a reduced flame temperature, enhancing the risk of interference problems. Interference through ionization occurs only in a few cases, for example, for alkali metals, and can be easily avoided by the addition of an easily ionizable element as an ionization buffer, such as sodium, potassium or cesium. There are about 30 elements that in effect cannot be determined with the air–acetylene flame since they form refractory oxides, such as aluminum and silicon. Such elements require a hotter flame in order to break the element–oxygen bond, such as the nitrous oxide–acetylene flame; this flame is operated with a slight excess of fuel, providing reducing conditions and a flame temperature of about 2975 K. Both flames can be safely operated, and modern instruments contain sensors and interlocks for fully automated operation.

Samples are introduced into flames normally in the liquid form by a pneumatic nebulizer and mixed in a spray chamber with the flame gases before these reach the head of the (premixed) burner, where they are ignited. The burner has a single slot of appropriate length providing a certain depth for the absorption volume (comparable to a cuvette length), that is essential for the sensitivity of the method. Absorption of light coming from a primary light source is directed through this absorption volume and is measured at an observation height in the flame

Table 1 Comparison of relative instrumental detection limits ($\mu g\,L^{-1}$) for FAAS and GFAAS (after Welz and Sperling[2])

some millimeters above the burner exit, where the atom concentration is at its maximum. Operational parameters to control flame atomization are very few (e.g. the flame stoichiometry, the nebulizer uptake and the observation height). Typical detection limits of FAAS are of the order of $1–100\,\mu g\,L^{-1}$ (see Table 1) and are similar to those obtained by radially viewed inductively coupled plasma optical emission spectrometry (ICPOES). The precision of measurements can be better than 0.3% using optimum conditions.

FAAS has found wide application in environmental analysis and is often still used as standard method. However, owing to its lack in sensitivity, its application is limited to the determination of the main and minor elements and some trace elements, especially for contaminated samples (sewage sludges, wastewater, sediments, etc.).

2.2 Graphite Furnace Atomic Absorption Spectrometry

GFAAS offers detection limits which are about a factor of 20–200 lower than for FAAS (see Table 1). This significant improvement is the result of the improved residence time of the atoms in the absorption volume, which is mainly dictated by diffusional losses from the tube. In principle, the much longer residence time should also lead to greater freedom from interferences, provided that atomization takes place under isothermal conditions. To come as close as possible to the ideal state of isothermal atomization, different efforts have been made, of which platform atomization is the most prominent. Platform atomization together with the use of a powerful Zeeman effect background correction (ZBC) system, fast signal evaluation and the application of matrix (chemical) modification, forms the basis of the stabilized temperature platform furnace (STPF) concept.[3] A step even further in this direction is the transversely heated graphite atomizer (THGA), which heats uniformly over the whole tube length avoiding any cold spots,[4] which are observed in longitudinally heated furnaces, owing to the necessity for cooling the tube ends for reasons of reproducible electrical contact.[5]

The disadvantage of GFAAS compared with FAAS is the lower sample throughput. In a graphite furnace system the measurement cycle starts with the injection of liquid samples (digest, extract, suspension, standard solution) of about $5–50\,\mu L$ into the graphite tube or into the cavity of a platform. Thereafter a temperature program is initiated, including drying, pyrolysis (thermal pretreatment for the decomposition of organic matrix or the volatilization of other matrix components), atomization (with temperatures up to 2800 °C), and an additional cleaning step to remove remaining matrix components from the furnace. The whole cycle takes typically about 50–100 s (i.e. about 10 times a regular FAAS measurement) and must be optimized for a particular analyte–matrix combination. During the steps of this cycle the furnace is flushed with an inert purge gas stream (argon is recommended) in order to protect hot graphite

parts against oxidation and to remove volatile reaction products. Other alternative gases such as air, oxygen and hydrogen can be added during the first steps, in order to facilitate thermal pretreatment. GFAAS is called a mature technique, not only with respect to instrumentation, but also with respect to methodology. Using STPF conditions together with integrated absorbance for signal evaluation, it can be shown that the characteristic mass (i.e. the mass of element in picograms that produces an integrated signal equivalent to 0.0004 A s) for various elements in different matrices differs by only around ±15% between different instruments,[6] offering a way towards standardless analysis (sometimes even called 'absolute analysis'). At least such possibilities can be used for semiquantitative analysis for screening purposes and for system diagnosis. With respect to environmental analysis, GFAAS is the standard method for many trace elements, especially for background values, and for unpolluted samples, such as fresh water and biological materials.

2.3 Other Atomic Absorption Spectrometry Techniques

Since neither FAAS nor GFAAS offers a particular detection power for mercury and hydride-forming metalloids such as antimony, arsenic, selenium, and tin, special vapor generation techniques to measure these elements after volatilization in the gas phase were developed and are commercially available. Mercury is commonly reduced, after digestion of solid samples or directly in liquids, to elemental mercury by the addition of stannous chloride or sodium tetrahydroborate and analyzed at ambient or slightly increased temperature by the cold vapor technique with detection limits at or below the micrograms per liter level. In a similar manner, the hydride-forming elements are measured by the hydride generation technique, in which the analyte is volatilized by reduction with sodium tetrahydroborate and analyzed by atomization in a heated QTA or after in situ trapping in the graphite furnace. These different vapor generation techniques often provide detection limits improved by a factor of about 10 in comparison with GFAAS of liquid samples. Disadvantages of vapor generation techniques are the additional sources of interference during the process of vapor generation and atomization, which for the case of QTAs takes place at temperatures limited to about 1000 °C. In order to reduce the problems with vapor generation, special attention has to be paid to sample preparation, for which the requirements are the most stringent in comparison with other AAS techniques. An extensive discussion of the hydride generation technique can be found in a monograph by Dedina and Tsalev[7] and a detailed discussion of both vapor generation techniques can be found in a monograph devoted to AAS by Welz and Sperling.[2]

The call for automation of the vapor generation techniques was one of the driving forces behind the development of using flow injection (FI) as a sample managing system for AAS.[8] The basic principle of using FI for the transport of sample solution for AAS is shown in Figure 2.

Nowadays the coupling of FI has been realized with all AAS techniques, including the GFAAS technique, with great benefits for AAS in many respects. FI can be used just for sample introduction in FAAS, improving the tolerance for high-salt matrices, but also can be used for sample dilution, calibration, separation, preconcentration and speciation in combination with all AAS techniques. The main advantages of FI for AAS can be summarized as its high potential for automation and its high repeatability and reproducibility of all the process. Further, FI provides a closed system, which reduces external contamination to very low levels and is operated under thermodynamically nonequilibrated conditions, which allow for high sampling rates. The ease of automation comes from the generally simple system, which normally consists of one or two independent multichannel peristaltic pumps, a multichannel injection valve, a manifold made from polymeric tubing, flow conjunctions, mixers, reactors, separators and columns, with all the active parts under computer control. Commercial systems are available and integration of FI into the AAS software has been realized.[9] Environmental analysis can greatly benefit from the coupling of FI with AAS in all cases where the automation reduces costly manpower or the sensitivity or selectivity of AAS alone is not sufficient for the analytical task. Examples of such applications will be briefly discussed in section 4.

3 METHOD DEVELOPMENT AND VALIDATION

3.1 The Analytical Task

Environmental chemical analysis very often is the basis of other environmental studies, such as risk assessments, or court actions, such as the withdrawal of allowances, involving decisions which have an enormous economic impact. In order for analytical results to provide the information necessary to support such decisions, confidence in the quality of the analysis must be sufficiently high. Those parameters that will influence the decisions, the data quality objectives (DQO) should be defined, in order to fit the analysis for the purpose. Two basic parameters should be considered when discussing analytical results: *accuracy* (closeness of the agreement between the result of a measurement and a true value of the measurable quantity of an analyte) and *uncertainty* (expressed as the confidence of variation or the confidence interval) due to random errors and random variations in the procedure.[10] While accuracy is of primary importance, an unacceptably high uncertainty renders the result useless. Apart from the requirements on the quality of the results, the whole analytical procedure must be designed to answer the questions of the analytical task in an economical way (i.e. it should be fit for purpose). Errors can occur in every step of an analysis and negatively influence its accuracy to a degree corresponding to their share of the entire method. In order to reduce such errors, it is of major importance that all steps of an analytical method are documented and that special attention is paid to steps that are particularly critical. Table 2 presents a general scheme of the analytical process for trace metal analysis, where the actual analytical procedure covers steps III–XI. When comparing the estimation of possible errors in each step, it becomes obvious that the most often discussed step, 'instrumental determination', is normally the most accurate and precise step of the analytical procedure, while the most critical step, the sampling, often is not even under the control of the analyst. It cannot be overemphasized that the analyst should have all the steps of a method under control since only then can possible problems be recognized, evaluated and, if necessary, remedied.

Table 2 General scheme of a trace element analysis

Step	Topic	Associated problems	Influence on final results[a]
I	Defining the analytical task	Defining the scientific problem: general association (degree of difficulty), extent (number of samples, frequency of sampling), urgency	++++++
II	Planning	Orientation of task on the potential of the laboratory (instrumentation, methods and staff; organizational structure and time schedule)	+++++
III	Sampling	Representativeness of the sample with respect to the objective of sampling; contamination during sampling, subsampling or homogenization	+++++
IV	Sample preservation	Contamination; losses; disturbance of speciation	++++
V	Sample storage	Stability of the constituents for short-, medium- or long-term storage (specimen banking)	++++
VI	Sample digestion or decomposition	Analyte losses due to volatilization or insufficient digestion; contamination from reagents and containers	++++
VII	Trace–matrix separation	Efficiency of separation; completeness of preconcentration; contamination from reagents and containers	++++
VIII	Instrumental determination	Suitability and performance of the selected procedure for the given analytical task; conditions of the instruments used	+/++
IX	Calibration	Selection of a suitable calibration technique; quality of the calibration samples and calibration solutions employed; adequate weighting of the blank values	++/+++
X	Data evaluation	Selection of all relevant values and statistics; sample identifiers	++
XI	QC	Adequate statistical control of all analytical steps; selection of appropriate QC samples; interlaboratory comparison	++
XII	Analytical report	Adequate assessment of the analytical results and QC	++
XIII	Interpretation	Adequate assessment of the analytical results with respect to the environmental task (ecochemical, ecological, geological, oceanographical, ecotoxicological, toxicological, occupational, epidemiological, etc.)	++++++

[a] + = 2–20%, ++ = 20–50%, +++ = 50–100%, ++++ = 100–300%, +++++ = 300–1000%, ++++++ = production of 'data cemetery'.
QC, quality control.

A number of rules for the conductance and documentation of an analysis, meant to facilitate achievement of such a goal, are generally summarized under the term good laboratory practice (GLP). Further, it is of equal importance to use methods which are fit for the purpose and are well known to the analyst. If such methods are available and validated, their performance has to be controlled throughout the whole duration of the analysis. The installation of a suitable QC program is often a part of the contract or, as many other aspects of environmental analysis, is part of national and international regulations. General guidelines for the installation of such programs are available.[11] In case of lack of validated methods, effective method development must take place, which has the role of detecting possible sources of errors and eliminating or reducing them to an acceptable level. Normally such method development starts by modifying existing methods rather than starting from scratch.

3.2 Sampling and Sample Pretreatment

3.2.1 Sampling

The analytical procedure starts with the removal of a portion from the material to be examined; this is the laboratory sample that subsequently will be analyzed.[12] During the sampling procedure, care must be taken to ensure that the laboratory sample is representative of the material from which the sample was taken or of the situation which is to be examined. Incorrect sampling renders even the most accurate analysis ad absurdum, a fact often underestimated, since the largest errors take place during sampling and cannot subsequently be corrected. In general, a differentiation can be made between two procedures for representative sampling: (a) random sampling and (b) systematic sampling. Random sampling means the random collection of individual specimens from a total parent population frequently aiming at the determination of an average value (e.g. collection of birch leaves from a birch forest to determine average calcium content at time x). Systematic sampling, on the other hand, mainly refers to problems of changeable values as a function of space and time (e.g. the collection of spruce needles of a certain age or from various levels of a spruce tree to determine the exposure to air pollutants), thereby coupling a specific systematic study to a random sample. Regardless, the following three fundamental sampling rules are valid for both types of sampling:

1. The sample taken from the system should have exactly the same chemical composition as the original material.
2. The probability of being taken as a sample from a total population or total mass of material must be equally great for each individual samples.
3. The greater the variability between individual samples and the greater the number of individuals or the greater the mass of material to be evaluated, the greater are the efforts required for sampling.

Generally, different sources of error prevent the first two fundamental rules from being fulfilled, such as problems with the sampling strategy (place, time, duration and method of sampling), the selection of the apparatus (contamination from the materials used, sorption losses), the execution (sampling, subdividing, homogenization, filtering, preservation) and delivery (transport, identification, protocol). The particular problems depend very much on the type of material or situation to be investigated, and therefore will be discussed later (see section 4).

3.2.2 Sample Preservation

If an analysis is to have any meaning, care must be taken to ensure that the laboratory sample is unadulterated during transportation to and storage at the laboratory while awaiting further sample pretreatment. The preservation of a sample in all of its complexity is impossible and therefore can only be replaced by a 'freeze' of selected properties of the sample, such as pH and pE values, as well as the contents of main and trace constituents, matching the needs of the given task. Microbiological activity must be suppressed just as much as analyte concentration changes caused by adsorption losses or contamination. Subdivision of the sample into a number of portions may be necessary if a number of constituents must be determined that require different stabilization. If a number of analytes are in a dynamic equilibrium (e.g. redox equilibrium), such as in speciation analysis, preservation is exceedingly difficult, if not one of the most difficult steps of the whole procedure.[13–15]

3.2.3 Sample Pretreatment

Since the risk of systematic errors increases with the extent of sample pretreatment, the number of steps and the mass of reagents used during such treatment should be kept to a minimum. Similarly, direct methods are preferred to methods which require extensive preparation such as separation and preconcentration. However, solid samples can generally only be directly analyzed relatively free of problems by GFAAS, so that a digestion is usually required prior to determination. Sample decomposition is prone to three different types of error sources: (a) incomplete dissolution, (b) loss of analytes by volatilization and (c) contamination by the reagents

(acids, etc.). Fusion and dry ashing are the most seriously affected with respect to volatilization losses owing to the higher temperatures employed, but acid digestions are not without problems. All digestion procedures performed in open systems are prone to external contamination, which can be best avoided by operation in closed vessels under pressure.

The risk of errors also increases with decreasing analyte concentration. For those cases in which a low analyte concentration requires separation and preconcentration, all steps should be either carried out under clean working conditions (clean room or clean bench) or performed in a closed system, such as provided by FI manifolds.

3.3 Atomic Absorption Analysis and Methods

It has been pointed out already that normally the determination step is the most accurate and precise step of the whole analytical procedure. However, such a general statement can be valid only if the determination step is following a well-developed method, using an appropriate technique and instrumentation that is well calibrated and maintained in good condition. Each of the AAS techniques (e.g. FAAS, GFAAS, HGAAS) has an optimum working range with respect to concentrations, analytes and matrices and should not be used outside this range. AAS is a relative technique in which quantitative determinations are performed by comparison with calibration samples (calibration solutions). Since changes in the instrument parameters, the condition of the instrument, and the conditions of measurement are reflected in the calibration and are thus eliminated (except drift), it is still possible to obtain quantitative results even when the sensitivity is far from optimum. Despite this possibility, working in this manner cannot be recommended since then substantial control of the condition of the instrument is lost. Apart from the fact that the performance characteristics of an analysis are degraded under these conditions, judgment of the analytical data is questionable since significant changes in the sensitivity or noise are indications of malfunctions of the instrument or errors in the method, which may lead to measurement errors.

3.3.1 Instrument Fault Recognition

The absence of instrumental faults is a prerequisite for a meaningful analysis. For this reason a protocol of the performance characteristics of every analysis should be carefully maintained, and any larger deviations from specified values or values in earlier protocols should be a reason to search for the cause.

Frequent causes of a lack of sensitivity in AAS are in general as follows:

1. dilution errors when making up the calibration solutions;
2. wrong or faulty lamp; too high a lamp current;
3. analyte losses in the stock or calibration solutions due to insufficient stabilization or unsuitable containers;
4. incorrect wavelength or too large a slit width;
5. matrix effects due to the use of either the wrong buffer or modifier, or the absence of either.

The following causes can be additionally present in FAAS:

6. wrong flame type or nonoptimized flame stoichiometry;
7. nonoptimized horizontal or vertical burner position;
8. clogged sampling capillary, nebulizer, or burner slot; incorrect aspiration rate;
9. unsuitable inserts in the spray chamber; misaligned impact bead.

Frequent causes of reduced sensitivity in GFAAS (enhanced characteristic mass) are as follows:

10. erroneous sample dispensing;
11. preatomization analyte losses; these can be due to a pyrolysis temperature that is too high or to either an unsuitable or missing modifier;
12. unsuitable (excessive) atomization temperature;
13. erroneous blank value or baseline correction;
14. too high a gas flow rate during atomization or the use of an unsuitable purge gas;
15. too low a heating rate; this can be caused by an unsuitable power supply or poor electrical contact of the graphite tube;
16. too low a magnetic field strength for ZBC (e.g. insufficient voltage at the electromagnet).

Much more seldom than decreased sensitivity is enhanced sensitivity (reduced characteristic mass). This can be traced almost without exception, especially in trace analysis, to accidental introduction of the analyte. If this occurs a systematic search should be made to determine the cause. All analytical results generated under such conditions, and also all corresponding publications, should be regarded with considerable scepticism.

Insufficient precision or excessive noise generally has one of the following causes:

1. low lamp energy; poor quality lamp;
2. wrong lamp current or poor lamp alignment;
3. wrong wavelength or too narrow a slit width;
4. contaminated optical components (windows, lenses, mirrors, etc.);
5. emission noise;

6. poor alignment of the line source and the continuum source for background correction;
7. inhomogeneous sample solution or slurry, the presence of suspended matter in the measurement solution, nugget effect for solids analysis.

For FAAS the following specific causes in addition to those above may be considered:

8. partially clogged nebulizer or burner; defective nebulizer;
9. contaminated spray chamber or inserts (large droplets on the surface are an indication of wetting problems);
10. irregular drain flow from the spray chamber;
11. irregular gas flow (e.g. too low a gas pressure);
12. unsteady flame caused by drafts, strong ventilation system, change of solvent, etc.;
13. an excessively short integration time or insufficient damping.

Specific causes of insufficient precision or excessive noise in GFAAS include the following:

14. irreproducible dispensing of the test sample solution;
15. spattering of the solution caused by either too rapid or incomplete drying;
16. irregular spreading of the measurement solution over the atomization surface (wetting problem);
17. aged graphite tube or contacts;
18. an excessive integration time or incorrect integration window;
19. baseline offset correction (BOC) too short or erroneous.

Finally, drift is often caused by one of the following problems:

1. changes in the radiant intensity of the lamp (or lamps) or of the line profile during the warming-up phase or in the event of a defect; changes in the ratio of the radiant intensities of the line source and the continuum source for background correction;
2. evaporation of the solvent from the measurement solution;
3. for FAAS, warming or cooling of the burner or the formation of encrustations on the burner slot;
4. for FAAS, changes in the rate of aspiration or in the efficiency of nebulization due to physical changes in the sample capillary or the nebulizer;
5. for GFAAS, aging of the graphite tube or the accumulation of residues (e.g. carbon from biological materials).

This list of frequent causes of marked deviations in the most important performance characteristics can only serve as a starting point for troubleshooting. Nevertheless, deviations of this sort are nearly always an indication of a malfunction or an operational error and must therefore be taken seriously. The important performance characteristics such as sensitivity (or characteristic mass or concentration) and the signal-to-noise ratio (S/N) should always be documented with the analytical results so that malfunctions or operational errors can be traced or eliminated. In modern instruments, functions such as monitoring the condition of the instrument and maintaining a protocol are performed automatically with the corresponding algorithms being implemented in the instrument software.

A convenient procedure for monitoring further instrumental functions in GFAAS, in addition to the sensitivity and S/N, has been described by Slavin et al.[16] Using a certified reference material (CRM) (Trace Elements in Water, NIST 1643b), the characteristic masses and the Zeeman factors for chromium, copper and silver are determined without a chemical modifier and under easily reproducible conditions; additionally the lamp energy is recorded. Copper exhibits the greatest loss in sensitivity at the 324.8-nm line when ZBC is applied and is very sensitive to changes in the magnetic field strength. This element can thus serve as an indicator for an insufficiently strong magnetic field. Chromium is a difficult to volatilize element and requires a relatively high heating rate; at the 257.9-nm line its determination is sensitive to emission interferences, which can indicate a poorly aligned graphite tube atomizer. Silver, on the other hand, is not noticeably influenced by the magnetic field strength, the heating rate or the alignment of the graphite tube. If the sensitivity of all three elements is influenced to the same degree, this is an indication of dispensing problems or that the actual temperature deviates markedly from the rated value. If this test is performed at regular intervals, it serves as a powerful tool to document the state of the instrument.

3.3.2 Instrument Optimization

Various strategies have been applied for optimizing the instrument parameters of AAS techniques, such as methods of experimental design,[17] simplex optimization[18] or complete response-surface mapping.[18] The use of such chemometric methods for optimization is useful, since running simple series of experiments changing one parameter at a time may lead to nonoptimum conditions. The situation is further complicated, since different performance characteristics can exhibit varying optima, so that compromise conditions may represent the practical optimum. For example, often it is the case that the conditions for optimum sensitivity are not the same as the

conditions for the best possible tolerance to constituents of the matrix. The required task must therefore be defined before optimization can be undertaken. Frequently, the task is to optimize analytical performance characteristics such as detection capability, precision, working range or tolerance to matrix constituents, but occasionally considerations of economics, such as high sample throughput, minimal manual effort, low sample or reagent consumption or low costs, are more important.

In FAAS we can observe that a burner position or a nebulizer which is optimized for maximum sensitivity can exhibit very low tolerance to matrix constituents. In the case that high sensitivity is not the primary objective, the nebulizer/burner should be optimized for high tolerance against matrix constituents. This is normally done by adjusting the nebulizer and its impact bead (if used) for generating mostly very fine droplets rather than for maximum aerosol density. Also, the observation height for the best sensitivity and the lowest interference effects might be different.

In GFAAS, the stabilizing effect of a modifier (e.g. palladium) can lead to a lower rate of atomization, so that broader signals are obtained than if a modifier were not used. Such signal broadening may lead to a deterioration of the S/N and therefore to a poorer limit of detection (LOD). On the other hand, the linear working range can be extended upward since the limiting absorbance is only reached at higher analyte masses, and the tolerance against concomitants is significantly improved owing to more effective separation during the pyrolysis step and the higher effective atomization temperature.

For samples that do not require the best detection limits achievable by GFAAS, the sample throughput can be enhanced and the analysis costs reduced.[19] This is possible by the reduction of the furnace cycle time. A set of strategies can be combined to achieve fast furnace programs: (a) reduction of the sample volume to the minimum for the required sensitivity allows for (b) shortening of the drying step and (c) if the sample matrix is not complex, for the omission of the pyrolysis step. The drying step can be further shortened if started already during sample dispensing (hot injection). For maximum throughput, the addition of modifiers can be either omitted totally or done in advance directly into the sample cups rather than the graphite tube.

A different strategy leads to improved detection power. Since the measurement signal of GFAAS is proportional to the analyte mass and not to the concentration, the detection capability can be improved by dispensing larger volumes of the measurement solution. When the upper limit for a single dispensing is reached, which is dependent on the particular design about 40–100 µL, multiple injections each followed by a drying step can be used with modern autosamplers to enhance the total sample mass further. The additional time required for these steps can be reduced by injecting into a preheated graphite tube.

The greatest improvement in sample throughput can be achieved by using simultaneous multielement analysis. However, multielement methods require particular attention to be paid to the optimization of the FAAS[20] or GFAAS[21] operational parameters. The conditions normally chosen for pyrolysis and atomization of various analytes in graphite furnaces differ significantly. This behavior appears to stand in the way of attaining acceptable compromise conditions. However, the selection of compromise conditions is relatively simple, since the most volatile analyte dictates the maximum pyrolysis temperature and the least volatile analyte dictates the minimum atomization temperature. Nevertheless, the use of a transversely heated atomizer with an integrated platform is decisive, since it allows one to apply STPF conditions for both volatile and nonvolatile elements. Losses in sensitivity and selectivity under such compromise conditions are much smaller than assumed when a modern instrument concept is applied. For example, the loss in sensitivity because of an increase in the atomization temperature above the optimum due to increasing diffusional losses[22] is partially compensated for by an increase in the absorption coefficient with increasing temperature. Furthermore, the signal narrows with increasing temperature, improving the LOD since shorter integration times lead to an improvement in the S/N.[22] All in all, only small losses in the detection capability by a factor of 2–3 are expected for multielement determinations, which can be tolerated in many cases.

3.3.3 Recognizing and Overcoming Interferences

As a result of a lack of selectivity, the presence of concomitants in the test sample can cause interferences in the determination of the analyte. An interference can influence both the mean value of the analytical results and the attainable precision. A false mean value may lead to measurement errors if it is not eliminated or if it is not taken into consideration in the evaluation report. Measures for the elimination can be instrumental, such as appropriate background correction, or the choice of a suitable calibration technique, such as the analyte addition method, or the use of chemical additives. According to the International Union of Pure and Applied Chemistry (IUPAC), two types of interference can be distinguished, spectral and nonspectral interferences. Spectral interferences are due to the incomplete isolation of the radiation absorbed by the analyte from other absorption or radiation sources. Nonspectral interferences directly affect the number of free analyte atoms in the absorption volume and can be further classified according to the place or time of their occurrence.

3.3.3.1 Spectral Interferences Since AA spectra are much simpler than those of optical emission spectrometry (OES), spectral interferences are encountered far less frequently than in OES. The following cases can be distinguished:

1. direct overlap of the analytical line with an absorption line of another element;
2. absorption of the radiation of the analytical line by gaseous molecules;
3. absorption by concomitants of other radiation from the radiation source (or sources) that is not separated by the monochromator;
4. radiation scattering caused by particles in the absorption volume;
5. thermal emission of concomitants in the bandwidth of the monochromator.

While the thermal emission of concomitants is generally corrected for in AAS by modulating the primary radiation source, the light still reaches the detector. In the case that the amount of light from this interfering source is significant with respect to the modulated light from the primary source, increased noise is detected, lowering the attainable precision.

Only a limited number of direct overlaps occur in AAS, and of the 38 cases reported[2] only 10 are related to primary analytical lines. In most cases the interfering element must be present in a large excess to cause false measurement, which has not been reported in environmental analysis.

Spectral interferences of type 1 and 3 can be observed more often and also have been reported for environmental analysis. When a continuum source is used for background correction, any concomitant that exhibits an analytical line within the bandwidth of the monochromator can absorb radiation from the continuum source to a degree corresponding to its concentration. This supposed background absorption is then falsely subtracted from the AA, leading to overcompensation and thus to a measurement error. In order to absorb significant amounts of the radiation from the deuterium source, the interferent must be present in high concentrations. Normally this type of interference can be observed in the determination of trace elements in metallurgical samples such as alloys. However, a few cases have also been reported for environmental samples, where the matrix element iron interferes with the determination of Pb 217.0 nm and Cd 228.8 nm[23] and Se 196.0 nm and Sb 217.6 nm[24] and aluminum interferes with the determination of As 193.7 nm[24,25] and Sb 217.6 nm.[24] Molecular absorption also can lead to interference, either directly by overlapping with the analytical line (type 2) or by absorbing radiation from the background correction channel (type 3). Particularly cumbersome are the interferences from P–O for the determination of arsenic, selenium and tellurium and from S–O for the determination of selenium.

Generally, problems arising from background absorption (interference type 3/4) are more frequent with GFAAS than with FAAS.[26] In flames, background absorption is rarely significant at wavelengths higher than about 240 nm, rarely exceeding 0.05 absorbance. In furnace analysis, background absorption can be significant at wavelengths up to 500 nm, exceeding signal levels of 2 absorbance units. Type 4 spectral interferences (light scattering) is caused by the condensation of the sample matrix (or the modifier!), by forming a smoke or mist. This event occurs when a huge amount of volatilized matrix reaches cooler regions in the absorption volume, caused by temperature gradients inside the atomizer.

The prerequisite to counter such interferences is to recognize them. Spectral interferences can be detected by changing to another alternative analytical line, by changing the slit width of the monochromator and by measuring a matrix blank solution that is identical to the test solution but does not contain the analyte. In GFAAS, careful inspection of the time-resolved absorption signal may give indications of spectral interferences, for example, when the analyte signal falls below the baseline or when the analyte signals shows minima coinciding with maxima in the background channel. To counter such interference problems, there are some complementary measures available to the analyst:

1. selection of the appropriate background correction;
2. optimization of the temperature programming;
3. use of chemical modifiers.

Interferences of type 2 and 3 can in general be compensated by ZBC with the exception of molecules showing a Zeeman effect.[27] Such behavior has been reported for the molecular species N–O in the determination of Zn 213.9 nm[28] and Se 196.0 nm[29] and P–O in the determination of Ag 328.1 nm, Cd 326.1 nm, Fe 248.3 nm, Hg 253.6 nm and Pd 244.8 nm.[30,31] For such cases the optimization of the method is the only measure to avoid these interferences. The goal of method optimization is either to avoid the interferent species (do not use phosphate modifier, phosphoric acid, in digestions or extractions) or to separate the analyte and the interferent species by optimizing the thermal programming of the atomizer and the use of appropriate modifiers.

3.3.3.2 Nonspectral Interferences Nonspectral interferences are those which have an influence on the number of analyte atoms in the absorption volume. In the case where the mechanism of the interference is known, the interferent can be classified by naming the place where it

is acting or the process in which it is involved, for example, condensed-phase interferences concern all processes with the liquid and solid sample until it vaporizes, while vapor-phase interferences occur thereafter. For example, a condensed-phase interference might occur in FAAS when the presence of a particular matrix influences the transport of analytes from the solution to the absorption volume. This would cause a transport interference by influencing the nebulizer uptake rate, its nebulization efficiency (due to changing viscosity and/or surface tension) or the transport of the aerosol from the spray chamber to the flame. Volatilization interferences can be observed in both FAAS and GFAAS. In FAAS this type of interference occurs when the analyte forms a specific compound together with the interferent, which shows a different thermal stability (most often higher stability) in the flame or is occluded in a matrix particle of a difficult to melt or volatilize substance. In GFAAS, the most common form is premature loss of the analyte during thermal pretreatment by forming a volatile species with the analyte. Vapor-phase interferences can occur in all AAS techniques when the fraction of analyte that is dissociated, ionized or excited in the vapor-phase is changed owing to the presence of an interferent.

The presence of such nonspectral interferences can be diagnosed by comparing the slope of the calibration graph for a standard solution with that obtained from the complex sample solution. Nonspectral interferences can generally be eliminated by matching the test sample solutions and the calibration solutions as closely as possible. A practical way of doing this is to modify the sample composition by adding a spectrochemical buffer to all solutions (in the case of FAAS, called ionization buffers or releasers depending on the type of interference to be overcome) or a modifier (in the case of GFAAS), counteracting the interference effect. Another practical way of matching samples and standards is the application of the standard addition technique, where the calibration graph is directly obtained from the sample by spiking it with known quantities of the analyte.

3.3.4 Method Development and Validation

A suitable analytical method must have been developed and adequately characterized before analysis can take place, that is, measures must be taken to ensure that major problems such as interferences or instrument malfunctions are recognized and eliminated, and that the method generates reasonably accurate results. In particular the following tasks have to be performed during methods development and validation:

1. check for contamination;
2. determination of the precision within a series and between series;
3. determination of the LOD and limit of quantification (LOQ);
4. determination of the linear working range;
5. check for possible interferences;
6. comparison of the analytical results with those from alternative methods;
7. comparative analyses with other experienced laboratories;
8. analysis of CRMs closely matching the composition of the target sample.

Since a contract laboratory can only select methods that have been adequately characterized, in principle it cannot accept chance analytical tasks.

3.3.5 Measurement, Calibration, Evaluation

The material obtained after suitable treatment or preparation of the laboratory sample is the test sample (or, if only analytical chemistry is involved, the analytical sample). A test (or analytical) portion is removed from this for analysis. If the sample is a solid material, it may be analyzed directly by solid sampling GFAAS. In most cases it is transferred into a test sample solution, by performing a digestion, extraction or dissolution. The test sample solution can be used directly or after further treatment steps, such as dilution, addition of buffers or modifiers, and so on, for the measurement. After having sorted out all the possible error sources during method development and instrument maintenance, only a few errors sources remain that may influence the final measurement. The measurement solution actually used for the measurement by AAS must be stable for the duration of the analysis. This is especially important if an autosampler with numerous sample cups is used, since the measurement solutions can stand for several hours before being analyzed. While solvent extracts with volatile solvents or complexes with unstable metal chelates are particularly critical, even aqueous solutions become more concentrated with time; this effect becomes greater the smaller is the volume of the sample container. The evaporation rate from 2-mL standard GFAAS autosampler cups at normal room temperature is about $35\,\mu L\,h^{-1}$ and can be reduced to about $10\,\mu L\,h^{-1}$ when the autosampler is covered, and additional containers filled with water for humidification are placed below the cover.[16]

Another significant source of errors for the instrumental determination is the calibration.[32] Errors occur mainly during the preparation of calibration solutions by dilution of stock solutions. The dilution error increases with both the number of dilutions and the ratio of the dilution step.[33] In order to reduce such errors, only calibrated volumetric devices of quality class A should be used or, better, the dilutions should be performed gravimetrically;

dilution factors of 1 : 100 per dilution step should not be exceeded. Another error source in calibration is the purity and stability of the stock solution, which especially for speciation analysis cannot always be guaranteed. Also problematic is the handling of any blank solutions, which often are misused as the zeroing solution for evaluation of the signal baseline of the instrument, but for which the pure solvent should be used.[34] Blank solutions must be analyzed in the same manner as other sample solutions, and the result for the analyte concentration of samples should be corrected accordingly. Further, calibration can be significantly in error if the wrong calibration function is used. This is especially the case when a linear calibration is assumed in situations where the calibration function is nonlinear.

3.4 Quality Assurance

The accuracy of a determination depends not only on the selection of a suitable procedure, but also on the stability of the performance characteristics of that procedure. In principle, two different strategies are applied to verify that both goals are met. QC is the mechanism of verifying the absence of errors, while quality assessment is the mechanism of verifying that the system is operating within known and acceptable limits.[35] Quality assurance (QA) for environmental analysis was a growing feature of the 1990s, as illustrated by the number of QA guidelines and systems which are currently being implemented. The increasing interest is also reflected in the launch of the journal *Accreditation and Quality Assurance* in 1996.

3.4.1 Internal Laboratory Operations

The quality of laboratory operations, in the most general sense, is measured by the dedication of higher management to emphasizing quality in a delicate balance with the ever-present demands of productivity. QC always requires a high level of effort and must therefore be accommodated to the DQO (i.e. the higher the requirements on the accuracy of a method, the greater is the effort required for QC). Nevertheless, higher costs for QC can be justified when costs in other areas are reduced, such as those caused by repeated measurements or by false results.

The first requirement for implementing a QA program is the organization of events in the laboratory following certain rules that are generally summarized as GLP and good analytical practice (GAP). GLP provides guidance in the organization of laboratory events and for the conditions under which laboratory investigations are planned, conducted and assessed. By maintaining a protocol and issuing a report of the investigation, the aim of GLP is to make procedures in the laboratory so transparent that they can be verified by third parties (e.g. regulatory authorities, clients). The scope of these rules are laid down in the chemical legislation in force in most industrial nations. The installation of such rules is most often part of the contract between the client and the laboratory. A detailed discussion on this topic is beyond the scope of this article and the interested reader is therefore referred to introductory monographs.[36] Maintaining all the rules of GLP is both expensive and requires a considerable increase in personnel. Some typical violations of GLP rules are as follows:

1. balances remaining uncalibrated;
2. failure in recertifying mechanical pipets;
3. use of pH buffers of unknown age or origin;
4. use of unsuitable purity standards;
5. application of software beyond its purpose.

On the other hand, GLP alone cannot guarantee the trueness and quality of analytical data. The final responsibility for QA still remains with the analyst. QC and quality assessment programs must be implemented and the rules of GAP must be followed in a laboratory to reach the DQO. The rules of GAP include the following:

1. performing the analysis with an adequate number of adequately trained staff;
2. the use of validated methods;
3. analytical instruments that are calibrated and maintained in good condition;
4. the use of CRMs for calibration;
5. an effective internal QA program.

As far as possible, effective QC should be incorporated directly into the analytical program. Analytical results cannot first be generated and then deliberations subsequently made about their quality. Typically, the more complex the sample, the greater the effort the laboratory should make with respect to QC. Depending on the DQO, the QC program must be designed either to maximize the probability of error recognition or to minimize the probability of a false warning. By trapping and excluding error sources such as drift, the QC program can lead to an improvement in the method performance.

In order to be effective, at least the following procedures should be part of the internal quality assessment:

1. characterization and optimization of the precision and accuracy of the calibration function;[37]
2. characterization of the blank values;
3. characterization of the instrumental repeatability (precision on replicates);
4. characterization of the method repeatability (precision on duplicate samples);

5. characterization of the method performance by analyzing a control sample of known analyte content (recovery);
6. characterization of the accuracy of the method by analyzing a CRM (recovery).

To assure that the method is under statistical control, the results of such performance checks are documented in the form of control charts. Control charts serve multiple functions,[38,39] including:

1. recognition of drift or malfunctions;
2. to uncover errors in sampling or sample preparation;
3. to decide, whether the analysis is fit for purpose;
4. to support the analyst with respect to his/her clients by assuring his/her results.

3.4.2 External Quality Control

Outside evaluation of the laboratory provides an opportunity for the laboratory to view quality from another perspective. The GAP rules include the following external QC:

1. regular participation in interlaboratory ('round-robin') trials;
2. quality assessment by an independent QA unit;
3. accreditation or other certification of the laboratory by regulatory authorities.

Regular interlaboratory trials are organized by several national and international quality programs, sending performance evaluation samples to the participants before an audit or as part of ongoing performance checks. An on-site audit by a third party group can be very effective in reviewing the installed quality programs.

4 ENVIRONMENTAL REGULATIONS AND METHODS

Environmental studies cover a broad range of disciplines, for example, analytical chemistry, geology and biology, and include several aims such as monitoring (routine analysis), research (studies of environmental pathways) and modeling. In many cases chemical analyses are the basis of these studies. Environmental analysis traditionally is divided into the analysis of water, soils and the atmosphere. Such 'classical' division cannot be strictly followed here in view of the multitude of different environmental samples originating from the different compartments of the 'environment' and the mutual interactions that can be expected between them (see Figure 3).

Figure 3 Schematic representation of our environment and the interactions that can be expected. S = sediments; I = soils and rocks; M = magma. (Reproduced by permission from Mitra.[105])

Nearly all types of sample materials can become the target of environmental analysis, at least when the material is disposed of as waste. In order to assign the most widely varying materials into suitable categories, three categories were chosen. The categories are based on the analytical methods used for their analysis, rather than the environmental compartment from which they are taken; the categories are (a) water samples, (b) solid materials of mainly mineral phases and (c) biological materials.

A particular characteristic of environmental analysis is that most aspects of the analysis, (i.e. the frequency of the analyses, the strategy and methods of sampling, the pretreatment and instrumental determination, the QC of analytical results and the data presentation) are governed to a large extent in the finest detail by laws, regulations and guidelines. An overview of prescribed analytical methods and of international and German standards was given by Hein and Kunze.[40] Since the analyst must procure and follow the original method exactly, in order to be compliant with these rules, details of such methods will not be presented here. Instead, information will be given that will point to the most important work.

Introductory information on environmental analysis is available in the form of monographs[40–45] and review articles.[46–52] Publications on the determination of individual elements in environmental samples are also available, for instance, for aluminum,[53–55] arsenic,[56–61] cadmium,[62–65] chromium,[66–71] cobalt,[72] copper,[73] lead,[74–78] manganese,[79] mercury,[80–85] molybdenum,[86] nickel,[72,87,88] platinum,[89,90] selenium,[91–95] tellurium,[92] thallium,[96,97] tin,[98,99] vanadium[100] and zinc.[101] Regular reviews of environmental analytical chemistry appear annually in the *Journal of Analytical Atomic Spectrometry*[102] and every second year in *Analytical Chemistry*.[103] The application of AAS in

environmental analysis has been recently reviewed by Sturgeon.[104]

4.1 Water Analysis

Although the compound H_2O is clearly defined for the chemist, the matrix 'water' offers an unbelievable multitude of forms for the analyst, reflected in the number of methods for its analysis. Water samples can be classified by legislators, analysts or users by the degree of its anthropogenic contamination (natural waters, processed water, polluted water, wastewater), by its salinity (fresh water, briny water, seawater), by its environmental compartment (atmospheric precipitation, surface water, groundwater, glacial ice) or by its intended use (drinking water, cooling water, bathing water, process water). Correspondingly, the palette ranges from highly pure waters to waters containing extremely high contents of impurities, with respect to both the analyte concentration and the matrix content. The parameters analyte concentration, total salt concentration and organic content are decisive for the procedure and the selection of the analytical technique.

Even though most natural waters contain over 99.9% of H_2O, accurate determination of elements in this simple matrix is frequently not as straight forward as would first appear. Most unpolluted natural waters contain less than $10\,\mu g\,L^{-1}$ of the commonly determined toxic metals and it is easy to obtain significantly biased results when measuring such low concentrations. The problem is obvious from the history of published concentrations of trace elements in seawater, which had decreased by around an order of magnitude within a decade. This is primarily due to (a) the improvements in the control of contamination during sampling, storage and analysis, and (b) the improved separation techniques and advances in the development of the instrumentation.[106] Therefore, the majority of data on the determination of the base concentrations of metals in seawater published before 1986 is practically worthless.[107] The same is probably true for other non-polluted waters and rainwater. Toxic metal levels in sewage and effluents are normally significantly higher than those of natural waters. However, interlaboratory comparison studies have demonstrated that inaccurate results at these higher concentrations can still occur unless meticulous attention to detail is observed in this case particularly to the control of interferences.

For an overview on water analysis, special monographs[108–112] and review articles[113] on this topic or more specific publications on seawater analysis[114–117] should be consulted. Review articles on the determination of trace elements in water are available for aluminum,[118–120] antimony,[121,122] iron[123] and mercury.[124] The journals *Water Research* and *Vom Wasser* (in German) deal exclusively with this subject.

4.1.1 Water Analysis and Legislation

As mentioned previously, environmental analysis is regulated to a large extent by national and international laws and regulations. Since water is a prerequisite for life, it is of primary concern. The different types of water meant to be consumed or used by humans or being discharged into the environment are extensively regulated and controlled. It is beyond the scope of this article to discuss such regulations in detail. However, some limits for a range of elements in treated (potable) water are given in Table 3 in order to discuss the applicability of AAS for the control of water quality.

In order to monitor for these elements at concentrations close to the limits set by regulations and to determine compliance, the LOD of the analytical technique should ideally be at least 10 times lower than the actual limit. By comparing the achievable LODs of different AAS techniques with these control limits, it is clear that FAAS can only be used to monitor directly seven of the 16 elements listed in Table 3.

4.1.2 Sampling and Sample Conservation

Appropriate sampling and subsampling techniques are a crucial prerequisite of the generation of meaningful

environmental data. The technique of sampling has to be selected in accordance with the requirements determined by the type of water that is to be sampled, such as piped water (drinking and industrial waters), springs and wells, groundwater (bore holes, seepage waters), flowing surface waters (canals, creeks, rivers, streams), still surface waters (ponds, lakes, barrages), marine waters and precipitation. The majority of still and flowing waters exhibit substantial variations in their element concentrations over time and in their spatial distribution. It is therefore relatively difficult to take a 'representative' sample. The required task must therefore clearly be established before sampling is undertaken. The simplest case is to take random samples, for example, at an outflow location at a given time. However, sampling of this type is only meaningful when the place and time of sampling are clearly defined, based on prior detailed information, and refer to a special situation. Much better information can be obtained for one or several analytes by determining the change in concentration with time, either continuously or at regular time intervals. For example, such sampling could be meaningful for the inflows and outflows of a sewage treatment plant. The degree of information can be further enhanced by a network of sampling points (e.g. along the length of a river or over the depth profile of a lake), and changes at each sampling point over the short term (days) or over the long term (months, years) are monitored. Multivariate statistical procedures can aid in the interpretation of such complex data.[125] Sampling strategies are described in numerous national and international standards,[40] some of which are given in Table 4, and also in a number of review articles.[106,113,126]

The collection of wet precipitation (rain, snow, cloud aerosols, etc.) is especially challenging,[127] particularly when the wet precipitate must be kept separate from the dry precipitate. For this purpose, rainwater collectors have been designed using a device that covers the collector during dry periods and opens only at the onset of rain[128–131] or by changing the exposed collection funnel by moving the cover at that moment.[132] Materials for such precipitation collectors have to be selected with care, since substantial errors can occur owing to adsorption on the walls of the collection funnel and sample container.[133] Collection time is also important, especially if an appropriate preservative has not been added.[134]

Also problematic is the collection of seawater samples from different depths or from the water surface, which contains high concentrations of surface-active compounds (biofilm). The ship itself and all the equipment used for sampling (winches, wires, bottom weights, samplers and messengers) are potential sources of contamination either due to their material or by their action (mixing different layers). These problems are discussed in more detail in review papers on seawater sampling.[106,135]

The sample pretreatment following the sampling of water samples depends on whether the total concentration or the concentration of dissolved analyte should be determined. In the first case, the water sample may have to be digested depending on its properties and the selected analytical technique. In the second case, the water sample is filtered after sampling, usually through a membrane filter of pore size 0.45 μm. Even such a simple task might not be without problems. Dissolved analytes might be lost during filtration owing to adsorption on the filter material or apparatus,[136] or the sample might become contaminated during filtration.[137] Various parts of colloidal forms of the analytes might pass through the filter, depending on the state of the filter with respect to loading with solid material.[138–140] For these reasons, those variations introduced during sampling of water are

often significantly higher than the instrumental variation of the measurement.[141] Immediately following filtration, or sampling if the sample is not filtered, the sample must be stabilized, usually through the addition of 10 mL of nitric acid per liter of water sample. The requirements for preservation are different for the different water samples (e.g. high salinity acts in a stabilizing manner), and also depend very much on the elements to be determined. In general, the pH value must be <1.5 in order to minimize the risk of analyte concentration changes due to precipitation or wall reactions. Different procedures may be required if individual element species are to be determined (see section 4.1.5). If the sample has been filtered, it may be of interest to examine the residue separately, following a method often very similar to those used for the analysis of sludges or sediments (see section 4.2).

Preconcentration at the site of sampling has been proposed as a strategy for sample preservation;[142] the claimed advantages are (a) large volumes of sample do not need to be transported, (b) concentrated samples are more stable and (c) the risk of contamination during transport and storage is reduced. The disadvantages are that preconcentration is a selective procedure, including only (a) selected elements, (b) mostly ionic species and often (c) only one oxidation state of the analyte, unless a comprehensive sample preparation procedure is performed at the sampling site. If interferences occur during preconcentration, it is very difficult to recognize them subsequently, since the original sample is no longer available. This strategy has not received wide acceptance and has only been used for special cases such as the determination of gold[143] and the determination of species of chromium[144] and mercury.[145]

Samples should be analyzed soon after sampling, especially when species determination is desired. Stabilized samples should be kept in appropriate containers, whereby the most suitable material depends on the target analytes and the concentration levels [details can be found in an overview published by Sturgeon and Berman[126]]. The best materials for the storage of samples with very low concentrations of analytes are fluoropolymers with a very smooth surface,[146] such as perfluoroalkoxy (PFA) [polyfluoroethylene (Teflon®PFA)][147–149] or polished polytetrafluoroethylene (PTFE) (Teflon®)[150] with the exception of mercury, for which glass is the best material.

4.1.3 Methods for Flame Atomic Absorption Spectrometry

According to most official methods for water analysis by FAAS, a digestion can be omitted if the analyte can be completely detected without such pretreatment. Normally, this is the case for filtered and stabilized water samples and often even for unfiltered water samples, provided that they do not contain large amounts of suspended matter that could block the sample introduction system or cannot be fully atomized in the flame. However, the direct analysis of water samples by FAAS is limited by its lack in sensitivity. Apart from the main elements sodium, potassium, calcium and magnesium, and under given conditions strontium, none of the trace elements can be determined in unpolluted surface waters, rainwater and seawater directly by FAAS. If the task is to monitor given limiting values, such as in the drinking water regulations or other corresponding international guidelines (see Table 3), then it is also possible in some cases to control for barium, copper, iron, manganese and zinc, and under given conditions for cobalt and chromium. For the analysis of some wastewaters, seepage waters or more strongly polluted surface waters in general, it is also often possible to determine elements such as cadmium, lithium, nickel and lead satisfactorily by FAAS. However, for such types of sample, a digestion is often indispensable.

By far the most often used digestion procedure for the determination of heavy metals in polluted waters by FAAS is digestion in nitric acid–hydrogen peroxide. Nitric acid and hydrogen peroxide are added to the water sample in a beaker and the volume is reduced to a wet residue, if required under repeated addition of hydrogen peroxide. The residue is taken up in nitric acid and water and the digestate is analyzed by FAAS.

In order to avoid potential interferences, to which especially the analysis of strongly polluted waters might be exposed, the following points should be particularly observed:

1. Background correction should be used for all determinations at wavelengths < 350 nm.
2. The nitrous oxide–acetylene flame should be used for the determination of chromium and is also strongly recommended for the determination of iron and manganese in water samples with complex matrices (e.g. wastewater), even if the sensitivity with this flame is poorer than that with the air–acetylene flame.
3. The addition of at least 2 g L^{-1} La as the chloride is required if calcium and magnesium are determined with the air–acetylene flame.
4. The addition of 1 g L^{-1} Cs as an ionization buffer is recommended for all determinations with the nitrous oxide–acetylene flame and also for the determination of sodium and potassium with the air–acetylene flame.
5. The operating conditions should be optimized for minimum interferences rather than for maximum sensitivity, particularly for strongly polluted waters.

If the sensitivity is then inadequate, a more sensitive AAS technique should be chosen (e.g. GFAAS).

Before GFAAS was introduced as a more sensitive technique in AAS, preconcentration by solvent extraction in combination with FAAS was used for the determination of trace elements in fresh waters. In this case complete digestion of the sample is essential. Nowadays, such methods are seldomly used routinely even though large numbers of these have been and continue to be published. The arguments against such methods are numerous (e.g. lack of sample throughput, involvement of too much manual work, contamination problems and the presence of interferences are only some examples). As a general rule, direct determination by other more sensitive techniques is generally preferred. A possible exception is on-line preconcentration,[151] for example, by sorption on packed microcolumns,[152–156] and this aspect is discussed in more detail together with GFAAS. Table 5 lists methods for the analysis of water samples by FAAS.

4.1.4 Methods for Graphite Furnace Atomic Absorption Spectrometry

With a sensitivity of about 2–3 orders of magnitude higher than that for FAAS, GFAAS offers the best prerequirements for the direct determination of a large number of trace elements in water. Also, digestion is not required for the majority of water samples, since in situ pretreatment such as oxygen ashing can be made part of the GFAAS heating procedure. Even water samples with a high content of suspended particles, which call for a homogenization directly prior to dispensing, can be directly analyzed with the aid of a slurry sampler.[170] The quantities of reagents and external

pretreatment steps can be thus reduced to a minimum for GFAAS, which is a prerequirement for accurate results in the extreme trace range. This reduction of sample pretreatment compensates for the often-cited disadvantage of GFAAS that the measurement time is relatively long and the sample throughput is low, which can be largely overcome by the use of state-of-the-art instrumentation, providing fully automated sequential or even simultaneous multielement analysis.

Another often cited disadvantage of GFAAS is its susceptibility to interferences. The relevance of such interferences, especially those reported in the early history of the development of the GFAAS methodology, has been greatly reduced with the introduction of the STPF concept by Manning and Slavin in 1983.[171] These and later authors showed that numerous trace elements in surface waters could be determined free of interferences against matrix-free calibration solutions by applying the STPF concept, including platform atomization, the use of matrix modification and ZBC.[172–174] Nowadays, many standard methods are based on a direct determination, such as EPA 200.9 for the determination of Ag, Al, As, Be, Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, Sb, Se, Sn and Tl and EPA 7010 for the determination of Ag, As, Ba, Be, Cd, Co, Cr, Cu, Fe, Mn, Mo, Ni, Pb, Se, Tl, V and Zn. Similar methods exist in Europe for Ag (DIN 38 406-E18), Cd (ISO 5961-1995, DIN 38 406-E19), Co (DIN 38 406-E24), Cr (ISO 9174-1990, DIN 38 406-E10), Ni (DIN 38 406-E11), Pb (DIN 38 406-E6), Se (DIN 38 405-E23), Tl (DIN 38 406-E21) and Zn (DIN 38 405-E8), and STPF conditions are recommended, even if they are not directly prescribed. Publications of direct determinations of trace elements in natural water samples are very numerous, and only selected papers are given in Table 6.

The probability of interferences increases with the complexity of the sample matrix and the requirements for low detection limits. Strongly polluted water samples usually contain a higher analyte content and therefore allow for substantial dilution, which greatly reduces interference effects during analysis by GFAAS. Mineral and therapeutic waters can nevertheless cause considerable analytical problems on occasion if they have a high matrix content, e.g. of sulfur compounds,[183,206] or when the analyte concentration is very low. Samples of such complexity require very careful method development, method optimization, validation and QC.

If the sensitivity of GFAAS is inadequate for the direct determination of trace elements in very pure water, the sensitivity can be markedly increased by using multiple injections[207–209] or by carefully reducing the sample volume by evaporation.[210–213] Nevertheless, while such procedures can easily be used for waters with low concentrations of inorganic or organic concomitants, more problems are expected when applied for wastewater, high-salt mineral water or seawater, so that the application for such samples is limited to cases where the analyte can be easily separated from the large amounts of matrix by thermal pretreatment.[214–218] Often, separation and preconcentration steps cannot be avoided for such complex samples.

The trace element concentrations in unpolluted seawater are in the lower micrograms to nanograms per liter range. From a comparison of the best published LOD for GFAAS with the trace element concentrations of two unpolluted seawater samples of different origins, one could conclude that it should be possible to determine a number of trace elements directly by GFAAS (see Table 7). However, an additional difficulty with seawater samples is the total salt concentration of $35\,g\,L^{-1}$ on average, which can lead to spectral and nonspectral interferences.

State-of-the-art systems providing high-performance ZBC together with STPF conditions are able to overcome these problems in some cases, as is demonstrated by selected publications on the direct determination of trace elements in seawater compiled in Table 8.

However, scrupulous optimization of the instrumentation and methods is necessary in order to reduce interferences to an acceptable level and to achieve the necessary S/N level. For this purpose the following points should be taken into consideration:

1. The STPF concept must be applied consistently to minimize spectral and nonspectral interferences. A THGA with integrated platform provides the best results.
2. As much of the chloride matrix as possible must be removed prior to atomization. The addition of ammonium nitrate or nitric acid as a modifier aids in vaporizing the chloride as NH_4Cl or HCl.
3. The thermal stability of volatile elements should be enhanced by the addition of modifiers (e.g. Pd) and/or the addition of hydrogen to the purge gas during the pyrolysis.
4. Since high background attenuation is to be expected, even when the matrix is largely removed, the application of ZBC is recommended.
5. A polarizer is not required for the longitudinal configuration of the magnet for ZBC. This configuration thus provides a better S/N than other configurations.

Even then, only a limited number of elements can be determined directly in seawater. For the others, as with the analysis of fresh water, preconcentration is indispensable. Great care is required to avoid errors at such a low concentration range $< 1\,\mu g\,L^{-1}$[113,126] owing

to contamination or analyte losses, and the following guidelines should be considered:

1. The number of necessary steps in the procedure, the number of containers, funnels, etc. and the mass of added reagents should be kept to a minimum.
2. All containers should be used exclusively for trace analysis and must be cleaned thoroughly prior to use, preferably by fuming out with nitric acid[240–242] or in the case of very clean PFA by leaching with dilute aqueous solutions of H_2O_2, ammonia and triethanolamine, which reveals comparable cleaning effects for this material.[243]
3. All reagents must be of the highest purity. If necessary, they must be further purified, e.g. by subboiling distillation.
4. All procedures should be performed in a clean room, clean work-bench or at least in a dust-free environment in a closed system, to minimize contamination from the laboratory atmosphere.

5. Polymer containers, funnels, etc. become aged with usage, developing active sites on the surface,[149] being able to exchange ions,[244] and therefore must be exchanged regularly for new ones.
6. On-line procedures in closed systems[151] are superior to all manual batch procedures owing to the significantly lower risk of contamination and to their much better repeatability and reproducibility.

For preconcentration, different techniques, such as liquid–liquid extraction,[245,246] coprecipitation,[247] ion exchange and solid sorbent extraction[48] electrodeposition,[249] might be considered, but some specialities have to be taken into account with respect to their combination with AAS techniques.[250] For the combination of solvent extraction techniques with GFAAS, the following facts should be considered:

1. Although organic solvents have the advantage of enhancing the sensitivity in FAAS, they tend to be a disadvantage in GFAAS since they often wet graphite and can spread uncontrollably.[251]
2. Organic solvents containing halogens are a potential source of gas-phase interferences.[252,253]
3. Organic solvents tend to evaporate from the sample cups, and some of the complexes extracted are unstable, calling for a back extraction into aqueous media.

The most often used methods for solvent extraction of trace metals from seawater are based on the use of dithiocarbamates as chelating agents.[254] A standard procedure is based on the use of equal amounts of ammonium pyrrolidine dithiocarbamate (APDC) and diethylammonium diethyldithiocarbamate (DDDC) at pH 4–5, which is adjusted with an acetate buffer.[255–257] Freon TF (1,1,2-trichloro-1,2,2-trifluoroethane) is chosen as an organic solvent because of its low toxicity, its

very low solubility in water (0.017% m/m at 21 °C), its quick separation from the aqueous phase and its low metal blank even at technical-grade quality.[256] Alternatively, the metal chelates may also be extracted into chloroform.[255,258] In order to overcome stability problems of the extract, the analytes are transferred back into acidic aqueous solution. This can be performed by either back extraction into dilute nitric acid[259] or by smooth evaporation of the solvent and acidic redissolution of the metals. Very high preconcentration factors of up to 6000 have been reported by such a combination of extraction and back extraction.[260]

Coprecipitation as a method for preconcentration has also often been combined with GFAAS determination, having its own advantages and disadvantages:

1. Carriers for coprecipitation are a potential source of contamination, since they are added in excess.
2. Coprecipitation carriers that can be easily vaporized or decomposed during the pyrolysis step are particularly suitable; these include elements such as indium, mercury, selenium[261] and tellurium[262] and organic reagents.[263–266]
3. Coprecipitation carriers, that act as modifiers, such as magnesium,[267,268] nickel[269] and palladium,[270] can also be advantageous.
4. The use of hydroxy precipitates[267,271–275] is preferred to that of sulfides,[276] which tend to create interference effects.
5. An interesting aspect of preconcentration by coprecipitation in combination with GFAAS is the direct analysis of the precipitate as the solid or a slurry.[263,277,278]

The use of ion exchangers and solid sorbents for preconcentration has found particular attention recently:

1. Column-based methods are particularly suitable for automation and even on-line methods are possible.
2. The sorbent can be used repeatedly, and often the amount of added reagent is reduced compared with other preconcentration methods.
3. Closed systems in general are easier to control for contamination. However, some ion-exchange resins and solid sorbent materials produce persistent and irreproducible blanks, owing to contamination of the polymeric material during its production.[279]
4. Organically bound metals might be lost during preconcentration, especially when using ion-exchange or solid-sorbent extraction, calling for a digestion procedure prior to preconcentration [e.g. ultraviolet (UV) photolysis].

Since ion exchangers seldom have the desired selectivity for the trace analytes, other solid-sorbent techniques have been developed, based on the use of more selective functional groups. At least two different approaches can be differentiated:

1. A chelating compound is added to the sample or preloaded on to the column. The column is often a hydrophobic (reversed-phase) material, which retains the chelating agent or the metal–chelate complex by sorption. Often used sorbents for this approach are silica C-18,[280,281] activated carbon[282] and macroporous resins such as Amberlite XAD-4.[283]
2. A functional group is permanently bound to the base material by a coupling reaction during the synthesis of the sorbent. Typical sorbents of this type are Chelex-100,[283] Muromac A-1[283,284] and 8-hydroxyquinoline bound to controlled-pore glass (CPG) or silica.[285]

A standard method using macroporous iminodiacetate chelating resin is available [EPA Method 200.13[286]] and can be used for the preconcentration of Cd, Co, Cu, Pb and Ni. Further details on solid-sorbent extraction techniques can be found in some review articles.[248,283]

On-line procedures especially for sorbent extraction with GFAAS detection, mostly based on FI, have been increasingly applied, using the same or similar sorbents as for off-line techniques. These on-line procedures offer a number of advantages:

1. The analysis time may be substantially reduced, since an equilibrium state is not needed.
2. There is a much lower risk of contamination since preconcentration and elution are performed in a closed flow system. Only inert materials and small surface areas are used, and the reagents can be purified on-line.
3. Since reactions such as acidification, complexing and sorption take place on-line and can follow each other in rapid sequence in a reproducible way, it is also possible to work with unstable complexes or intermediate products.
4. All processes can be easily automated.

On-line preconcentration procedures have made possible the determination of trace elements in the lower nanograms per liter range in seawater on a more or less routine basis. Commercial instrumentation including the necessary software, allowing for the coupling between FI and GFAAS, is available.[287] Proposed methods are based on the use of the reversed-phase sorption of chelate complexes with

dithiocarbamates[288–290] or dithiophosphates,[291] immobilized 8-hydroxyquinoline[292] or Muromac A-1.[293] An overview of such techniques was given by Fang and Tao[284] and progress has been reviewed by Fang.[294]

4.1.5 Methods for Speciation Analysis

Speciation analysis is an area which has found increasing interest in the 1990s. Element species can be distinguished by their oxidation state (redox species), by their molecular form (organometallic compound), by coordination (complex), by the phase in which the analyte exists (dissolved, colloidal, suspended) or by its solubility (leachability, bioavailability). In this broad sense, the analysis of filtered water samples is in principle already a form of speciation analysis. This physical separation can be refined to a fractionation of particulate and colloidal species via multistage filtration and ultrafiltration[295] and can be automated by means of FI-type manifolds[296] or field-flow fractionation. Methods used for such a type of speciation for water samples have been reviewed by De Mora and Harrison.[297] Considerably more detailed deliberations on the term 'species in aquatic systems' can be found in the monographs by Batley,[298] Krull,[299] Ure and Davidson[300] and Tessier and Turner.[301] In this section, however, the focus is on chemical species such as redox species and organometallic compounds. Very few direct methods exists for the determination of such species. More often, separation techniques have to be combined with suitable detection techniques. As far as speciation analysis is concerned, the FAAS technique lacks sensitivity, whereas the more sensitive ETAAS is not particularly suitable for detection in gas chromatography (GC), high-performance liquid chromatography (HPLC), and other chromatographic techniques most often used for the separation of trace element species. Therefore, AAS techniques can be ranked in the following decreasing order of their potential for speciation: HGAAS > CVAAS $\gg$ ETAAS > FAAS.

Since vapor generation techniques (HGAAS and CVAAS) are not the topic of this article, only speciation by ETAAS and FAAS techniques will be discussed briefly. Both techniques have been used in the past as detection methods for chromatographic separation techniques, as discussed by Ebdon and Hill,[302] but have been overtaken by more powerful detection techniques such as inductively coupled plasma mass spectrometry (ICPMS). Although FAAS and GFAAS are not very suitable to be coupled directly with chromatographic separation techniques, their combination with nonchromatographic separation methods is more straightforward, as we have discussed already for the case of preconcentration. Techniques such as solvent extraction or solid-sorbent extraction used for preconcentration can also be used for speciation purposes, for example, when the separation process is selective for one oxidation state of the analyte. Such combined methods, using GFAAS for speciation analysis, have been reviewed by Das and Chakraborty.[303] Often such nonchromatographic separation methods can be automated by using FI manifolds. When used for separation, FI provides only limited separation power, which mostly is exploited for binary separation of the type retained/not retained, for example, for preconcentration. While such a technique is not very well suited to separate a great number of analytes, it seems well fitted for screening purposes requiring high sample throughput. Further, for cases where the separation of species can be reduced to two, FI can be successfully used for speciation analysis. This is actually true for many cases of speciation of oxidation states of metal ions and metalloid ions, where the chemistry of these elements normally allows only for the presence of two different oxidation states in the presence of each other, at least under normal environmental conditions. Methods have been developed for the determination of As(III)–As(V),[304] Cr(III)–Cr(VI),[305–309] Fe(II)–Fe(III),[310] Sb(III)–Sb(V),[311] Se(IV)–Se(VI)[312] and V(IV)–V(VI).[313] The approach of binary separation can also be used for those cases where interest in the degree of speciation can be reduced to a binary differentiation. For example, such limited separation is useful for the differentiation of inorganic and organic species, labile and stable complexes, bound and free element species or the particulate and dissolved part of the analyte. This approach can also be applied for cases when other characteristics of the species can be grouped into two different categories, such as toxic/nontoxic. In this area of binary speciation, methods have been developed for the determination of free and complexed Cu[314] and of free and complexed Al.[315]

4.2 Soils, Sediments, Sludges, Coal, Dust and Other Solid Materials

A variety of widely differing solid materials will be discussed here together, simply because they have some common steps in their analytical procedure while differing in others. Solid materials such as arable soils, contaminated soils, sediments from rivers, lakes and seas, atmospheric dust and waste materials such as sewage sludge, ashes and other solid wastes are collected as samples from different compartments of the environment in order to gain information about the status of that compartment or to learn about the fluxes between them. The emphasis of environmental analysis is on the anthropogenic part of these fluxes and on the impact of such fluxes on the biosphere.

With respect to soils, in addition to the native content, various amounts of metals and metalloids are supplied

to the soil by dry and wet atmospheric deposition, by agronomic practices via fertilizers, sewage sludges or irrigation water, and so on and by waste discharges or waste disposal. For certain metals the anthropogenic proportion constitutes only a fraction of the natural amount, for others it can be the exclusive source. These metals and metalloids enter the food chain mainly via plant uptake.

Human activities are connected with the 'production' of waste materials including municipal solid wastes, industrial by-products, sewage sludge, dredged material, wastes from mining and smelting operations, filter residues from wastewater treatment and atmospheric emission control, ashes and slags from burning of coal and oil and from waste incinerators. All these wastes pose most challenging problems (e.g. when disposed of on land), creating a potential source for contamination of the soil and the groundwater.

The materials on the lake, stream and ocean floor, known as bottom sediments, are both a sink and a source of contaminants. Sediment-associated contaminants can be transported by resuspension of sediment particles, may accumulate in the food chain or may affect the health of biota and water quality in aquatic ecosystems. Knowledge of the character of the sediments and the fluxes involved is necessary for an understanding of environmental cycles but also in the development of techniques for remediation of aquatic ecosystems or the disposal of the sediments in the dredging of harbors and waterways.

With respect to atmospheric emission, monitoring frequently starts at the raw material stage. For example, emission monitoring of coal-fired power stations, coke works, incineration plants or cement furnaces starts with the analysis of the coal or waste materials to be burned. For the mass balance for such thermal reactors the different streams must be analyzed. While the mass carried with the scrubbed gases is important for the actual emission, the dusts collected in cyclones and electrostatic separators, ashes and other combustion residues such as slags must also be analyzed to characterize the complete system.

Air pollutants can occur in gaseous, fluid (dissolved or suspended) or solid form. Air must therefore be considered as an inhomogeneous, multiphase aerosol, whose composition is subjected to considerable spatial and temporal variations.[316] With respect to metals and metalloids, the gas phase is only of limited interest, since only mercury and a small number of volatile species occur as gases or vapors, especially close to hot emission sources.[317] The liquid phase (rain, snow, etc.), also termed wet deposition, belongs analytically to the area of water, which has been discussed in section 4.1. The analysis of air, with the restrictions mentioned already, is thus largely limited to the analysis of airborne dusts. Looked at globally, the bulk of airborne particles (approximately 90%) are derived from a number of natural sources (terrestrial, marine, volcanic, biogenic),[318] whereby salt from the oceans makes the largest contribution with about $10^9\,t\,a^{-1}$. Looking more specifically into metal emission, the view changes drastically, with a clear dominance of anthropogenic sources of the most important trace elements such as As, Cd, Cu, Cr, Pb and Zn on the global scale.[319] The anthropogenic sources of particle emissions (combustion, industrial, automobile) are by no means evenly distributed, but are related to the typical conurbations in which human activity is the most pronounced. Owing to the relatively high population and industrial density, such sources are concentrated in the northern hemisphere, but because of long-range transport globally these sources have an impact on a large proportion of the population in the form of pollution.[320]

4.2.1 Sampling of Solid Environmental Materials

Obviously, the procedures for sampling, sample homogenization and preparation of such widely differing materials are correspondingly manifold, and cannot be discussed in great detail here. Before one even starts to discuss analytical details, the exact purpose of the analysis should be clarified, since the type of information needed is decisive for the selection of the method. Three general procedures can be distinguished for these samples, determination of (a) the total concentration of an element, (b) the extractable portion and (c) individual species, especially organometallic compounds; the boundaries between these procedures are naturally flexible. The decision about which method to select is driven by the emphasis given to topics such as risk assessment, evaluation of bioavailability or toxicity, pollution control, baseline mapping and transport phenomena. The interested reader is referred to introductory monographs and review articles on the analysis of soils,[321–324] sediments,[325,326] sludges and other waste products,[327,328] and airborne particulates,[329] and on speciation analysis in soils and sediments[330–332] and to general treatises on environmental analytical chemistry, discussing such questions in more detail. The selection of the determination technique (FAAS, GFAAS, etc.) is simple in comparison. It is largely determined by the concentration of the analyte and also by the nature of the matrix.

4.2.1.1 Sampling of Soil, Sediments, Sludges and Solid Waste Materials The problem for sampling soils,[333–337] sediments,[338–341] sludges[328,335] and other waste materials[328,342,343] is the removal of a few grams that should be representative of the situation being investigated from a material that is present to the extent of tons or cubic meters. Meaningful sampling of such

heterogeneous media requires an understanding of the spatial and temporal variations, which is a prerequisite for answering the basic questions of how many samples are needed and where they should be taken. In the case of soils and sediments the planning of sampling has to start with a site investigation making use of available (e.g. historical) information, which could help to build hypotheses and conceptual models. A site characterization follows, consisting of two major steps, namely site observation and subsequent site mapping. Such site characterization is a multimedia, multidimensional, multidisciplinary effort, that requires vigorous communication among all of the principal parties involved and often includes preliminary sampling. Unfortunately, no checklists are capable of addressing all of the important issues and factors that influence the sampling and analysis of such materials. However, field guides and handbooks are available for soils[334] and sediments[344] that are helpful in defining the task. From all this information a sampling strategy is built, leading to a sampling network design. Depending on the required information, the sampling strategy must consider the local inhomogeneities in the horizontal plane of the sampling site, the dependence of the element distribution on the depth of sampling and possible seasonal variations.[167,345,346] A number of statistical procedures have been elaborated to facilitate representative sampling or to estimate the analytical uncertainty due to sampling errors, for example, in order to characterize contaminated areas.[347–352] Usually a large number of individual samples of the material being investigated are taken from different places (e.g. 25 samples from an agricultural field not bigger than 5 ha) and then combined into a composite sample. The advantages of composite sampling are that it reduces the cost of analysis and provides an estimate of the mean concentration. Its disadvantages are a loss of information about variation and the time required for such pretreatment. In order to avoid sampling errors[353] due to the heterogeneity of the material and the effect of particle size on element distribution,[354,355] one has to follow certain rules dictated by the particulate sampling theory, such as that developed by Gy.[356] In order to create an analytical subsample, the composite sample has to be homogenized and reduced in size. Different techniques for such homogenization exist, such as cone and quartering, sectorial splitting, riffling, milling and sieving. Sample preservation then depends on the analysis. In the case of total element determination the material is often dried and for other cases the samples are simply cooled to 4 °C or frozen (usually at −20 °C). The problems of sampling and sample preservation naturally become even more complex when element species are to be determined.[357,358] In any case, the uncertainty introduced by sampling of such heterogeneous materials supersedes all other following contributions,[339,359,360] and therefore needs careful evaluation in order to create meaningful data. It should be mentioned once again that this area is regulated by national and international rules, for example, for the sampling of soil (ISO-TC 190/SC2), sediments (DIN 38 414-11/1987) and sludges (DIN 38 414-1/1986).

4.2.1.2 Sampling Dusts Collecting the sample is the most critical step in the analysis of dust, as it is for other samples in environmental analytical chemistry. For the analyst, air is a practically infinitely expanded aerosol on which random investigations must be performed according to defined spatial and temporal regulations. The number and size of the random samples, as well as the place, time and sequence of sampling, are decisive for a representative statement on the relationship between quantity of material, space and time. A number of authors have treated the subject of sampling dusts very thoroughly in review articles and book contributions. This has been done either in general[361] or in selected areas such as the free atmosphere[316] or at the workplace.[362–364]

For the investigation of trace substances in the free atmosphere, the temporal and spatial distribution of sample collection in an area to be investigated must be matched to the meteorological conditions, such as wind direction, wind speed, air temperature and humidity. The length of an investigation program, the measurement frequency and the density of monitoring stations have to be carefully selected. Frequently, the concentration of constituents determined by a measurement program is influenced by the geographical location of the monitoring station. This is typical in areas where dust is whirled up strongly or close to the coast where the constituents of the sea spray become clearly noticeable. The extent to which meteorological conditions can influence sampling can be seen when the wind velocity is high, causing turbulence at the sampling port or even causing an under pressure so that the collected sample material can be transported back to the outside.

Dust cannot be sufficiently characterized by only its general composition, but physical and chemical forms (species) have to be differentiated;[365,366] the morphological composition of dust can be very heterogeneous depending on the origin of the particles[364,367] and the various forms can have markedly varying physiological activity. Smooth globular grains have a much smaller surface area, and are thus less reactive than needle-shaped, fine crystalline particles. Apart from the morphology, the size of particles, ranging between 0.001 and 150 μm, also has a decisive influence on the physiological activity. Particles smaller than 10 μm can enter the lungs of humans or animals, while larger particles can be filtered out. Dust samples often show a particle size distribution with characteristic maxima at two or three different particle sizes (bimodal, trimodal size distribution) depending on

sources and history. A further criterion is the solubility, which decides whether an element can directly enter the nutritional chain, or whether it is initially sedimented.

For sampling aerosols, two different approaches are available: procedures that use suction and those that do not. For the latter, various collectors for dust precipitates are available, which again are often regulated by national standards. In general, such devices do collect preferentially larger particles since these fall out more easily than smaller particles.

For sampling under suction, measurement and maintenance of a constant volume stream by the air pump are essential components of sampling. The sampling method most widely used is the high-volume sampler, which has been standardized in many countries, and operates at sampling rates between 40 and 100 $m^3 h^{-1}$. For sampling gaseous constituents, wash bottles with a suitable absorber solution or tubes being coated with a specific agent, so-called denuders, are frequently used. To separate dust from the air, flat membrane filters made of cellulose materials are most suitable owing to their low and constant element blank values. In high-volume samplers large filters can be used, which later can be cut to several aliquots that can be used for (a) various types of analysis, (b) replicates, (c) sharing samples with other groups or (d) storing them as 'backup' samples. Fiberglass filters do allow a larger volume of air to be taken through, but are less useful for trace analysis of airborne dust because of their high and often markedly varying element blank values.[368] Preseparating inlet systems are available for such samplers, which exclude particles larger than 10 μm, for example, in a cyclone. Cascade impactors most often are used for size separating sampling, which are available with 4–9 stages having size ranges between 0.02 and 20 μm.[361,369,370]

Sampling for emission measurements is usually performed directly in the stack or chimney, for example, of a power station or a waste incineration plant. The difficulties to be expected in taking a sample representative of the total mass flow under isokinetic conditions can be seen from the example of a stack gas stream of several 100 000 $m^3 h^{-1}$ at a temperature of up to 300 °C and with a varying dust content from milligrams to grams per cubic meter. For trace analysis, the problems of the level and scatter of the blank value and also contamination during sampling can additionally be detrimental to the results of the examination. This is more so the case for emission measurements since cellulose filters cannot be used, owing to the high temperatures at the sampling point, and quartz wool must preferentially be used.

For the measurement of dust at the workplace two different strategies exist, using either stationary or personal dust measuring instruments. Stationary measuring instruments are similar to those used for measuring in the free air and have the advantage that the air throughput is relatively high at about 20 $m^3 h^{-1}$, permitting a sampling period of only a few hours. The relatively small personal measuring instruments, on the other hand, have an air throughput of only about 120 $L h^{-1}$ (corresponding approximately to the volume of air breathed), so that sampling is required for the entire length of a working day to collect sufficient material for the subsequent chemical analysis.[362,364,371] Membrane filters made of cellulose materials are used preferentially for dust measurements at the workplace.

In addition to the collectors mentioned so far, which are largely standardized, there is a wide range of collectors designed for special applications, such as the investigation of automobile exhaust gases[372] or soot from Diesel engines,[373] or those that are specific for the subsequent analytical technique. Among these in particular are those developed for GFAAS procedures in which a probe[374] made of porous graphite is used as a filter and inserted directly into the atomizer, or the inner wall of the graphite tube itself is used for collection of aerosols either by impaction or by electrostatic deposition.[375,376] Owing to the high sensitivity of such in situ sampling techniques, very short collection times are possible so that the measurement can be performed virtually in real time. The disadvantages are that only one element can be determined per sample collection, except in simultaneous spectrometers, and that no sample is available for further evaluation. In general, procedures of this nature must therefore be seen as complementary to the standardized collection procedures and not as alternatives. A list of methods approved by United States Environmental Protection Agency (USEPA) was given by Kao,[377] but those for metals are few, however.

4.2.2 Determining the Total Concentration of Analytes

4.2.2.1 Total Dissolution For the determination of the total analyte concentration in a test sample, very harsh decomposition procedures are required, which are aimed at the total dissolution of the sample. Soil and dust samples exhibit considerable variations in mineralogical and chemical composition, including very resistant materials, making the task of total dissolution a difficult one. The total dissolution procedures available for such samples are either fusion methods using sodium carbonate[378–380] or lithium metaborate,[379–383] or acid digestions in the presence of hydrofluoric acid and frequently also perchloric acid.[380,384–386] Although such harsh procedures are time-consuming and the use of such dangerous acids demands special safety measures, they cannot ascertain the total dissolution of a number of minerals, such as cassiterite, chromite, zircon, rutile, monazite and corundum.[387–389] Apart from incomplete

dissolution, formation of volatile fluorides is another possibility for analyte loss for a number of elements such as antimony, arsenic, boron, germanium and silicon (which should be removed in this way).

Since fusion methods lead to high total salt concentration with a corresponding risk of contamination and interferences in GFAAS due to the high background signal, wet digestion methods are more popular in connection with AAS. However, often the difficult matrix cannot be dissolved by a single-stage dissolution, but calls for a combined multistage digestion using oxidizing acids (nitric acid, perchloric acid, sulfuric acid, hydrogen peroxide) and hydrofluoric acid.[386,390] If necessary, dry ashing can be performed in advance[391,392] and if insoluble, fluoride-containing residues are produced during digestion, they can be taken back into solution by the addition of boric acid.[390] A comparison study concluded that the combination of an acid decomposition with final fusion of insoluble residues is the best method for the hard to extract elements Cr, Y and Zr.[378]

Membrane filters normally used nowadays in dust collectors dissolve in nitric acid and also in organic solvents such as benzene.[371] On the other hand, quartz wool used as a filter medium for emission measurements usually requires digestion in nitric acid or hydrofluoric acid under the addition of hydrogen peroxide.[393]

For the digestion of coal and coal ash often a pressure digestion with hydrofluoric acid–nitric acid[394,395] is used, preferentially with the addition of a strong oxidant such as perchloric acid or ammonium peroxodisulfate.[392,394] Less common is a digestion with perchloric acid (72%) alone, which requires a good deal of attention.[396] The combustion of coal in an oxygen bomb[397] or oxygen combustion[398] and fusion with lithium metaborate[399] have also been described. In a review article, Mills and Belcher[400] discussed in detail the problems of sample pretreatment and digestion for the analysis of coal and ash.

4.2.2.2 Partial Dissolution In general, total dissolution is a difficult task for many samples and, once achieved, leads to high salt concentrations. The latter may pose problems with nebulization in FAAS or create strong background attenuation in GFAAS. The high matrix concentrations require regular blank controls to be performed, and frequently the calibration solutions must be matched to the matrix contents. Owing to such problems, it is very common to avoid 'total dissolution' in environmental analysis. Instead, an extraction with a strong mineral acid such as boiling aqua regia under reflux is preferred.[401–406] This is justified on the assumption that heavy metals insoluble in aqua regia will probably not be relevant for environmental chemistry, at least not in the short term. With the exception of a few cases, a valid approach seems to be that the aqua regia-resistant compounds will not be taken up by plants and cannot be dissolved by water or bacteria.[405]

4.2.2.3 The Microwave Oven Option Microwave-assisted digestions (MWDs) have found rapid acceptance in the environmental analysis of solid samples.[407–409] The major advantages of MWDs are reported to be the substantially shorter digestion times,[410,411] the lower risks of contamination, the reduced reagent requirements[412] and the lower risk of losses.[413] Different acids and acid mixtures have been investigated, mostly using nitric acid or mixtures of hydrochloric acid and nitric acid[414–416] or aqua regia,[417–419] but also including hydrofluoric acid[415,420–423] and perchloric acid.[424] While the careful selection of the acid mixture and the operational parameters was a prerequisite for a successful digestion until recently,[425] the development of systems with automatic pressure and/or temperature control[426–428] have significantly reduced such requirements. Owing to the high effectiveness of MWDs it has also been possible to incorporate them on-line in a flow system with FAAS[429–431] or GFAAS[432] detection.

For the actual determination by AAS, we should always remember the general rule that the best results can be expected when the optimum concentration range is used. This means that FAAS is only suitable for the determination of higher analyte contents, and not for trace analysis. Owing to the frequently complex and refractory matrix, particularly when the digestion is complete, the hottest possible flame should be used in general and the measurement should be performed as high above the burner slot as possible. In other words, the measurement should be optimized for minimum interferences and not for maximum sensitivity. Aqua regia extracts can be analyzed by FAAS relatively free of interferences, since the element concentrations normally to be expected in soil, sediment and dust samples are so high for numerous analytes that the sensitivity of FAAS is fully adequate. Some selected publications of such applications are given in Table 9.

The alternative way of avoiding interferences is higher dilution followed by GFAAS determination. The concentrations of elements in soils, sediments and sludges which are considered to be tolerable depend strongly on regional regulations, but in general they are between 1 and 300 $mg\,kg^{-1}$ for agricultural soils and about a factor of 10 higher for sludges.[455] Owing to the dilution introduced by the acid extraction, such soil concentrations produce solution concentrations between 10 and 3000 $\mu g\,L^{-1}$. Even one tenth of the tolerable concentration is still above the detection limit of GFAAS for most elements. The partial dissolution and the high dilution factor ensure that the matrix concentrations in the sample solution are often

Table 9 Selected publications on the determination of metals and metalloids in soils, sediments, sludges, dust and solid waste by FAAS

Analyte	Test sample	Remarks[a]	Refs.
Ag	Soils		433
Al, Ca, Fe, K, Mg, Na, Si	Coal, fly ash	$Li_2B_4O_7$ fusion	434
Ba, Be, Cr, Cu, Li, Mn, Ni, Pb, Sr, V, Zn	Coal, coke, fly ash	Australian Standard Method AS-1038	435
Be, Ca, Cd, Co, Cu, K, Li, Mg, Mn, Ni	Coal	Pressure digestion, $HNO_3-HF-H_3BO_3$	436
Ca	Soils	Addition of lanthanum	437
Cd, Co, Li, Pb	Coal, ash	Dry ashing/pressure digestion, $HNO_3-HF-HClO_4$	392
Cd, Cu, Fe, Mn, Pb, Zn	Sewage sludge	Microwave-assisted extraction	438
Cd, Cu, Pb	Soils, sediments	FI on-line sorbent extraction with DDTC/silica C-18	439
Cd, Cu, Pb, Zn	Sediments (lake)	Extraction overnight with $HCl-HNO_3$	440
Cd, Pb	Soils	Background interference by iron	23
Cd, Pb, Hg, As	Soils, waste	FI on-line dilution	441
Co	Sewage sludge	German standard method DIN 38 406-E24	442
Cr	Soils, sediments	Interferences, optimization of flame conditions	443–445
Cr	Sediments	Digestion problems	446
Cu	Sewage sludge	German standard method DIN 38 406-E7	447
Cu, Cr, Ni, Pb, Zn	Sewage sludge	Dry ashing at 450 °C	448
Cu, Mn, Pb	Sewage sludge	FI microwave-assisted on-line digestion	429, 449, 450
Cu, Zn	Soils	Microwave-assisted pressure digestion	411
K	Sewage sludge	German standard method DIN 38 406-E13	451
Mn	Soils, silicate materials	Digestion, $HF-HClO_4$	452
Na, K, Ca, Mg	Soils	FI on-line dilution	453
Ni	Sewage sludge	German standard method DIN 38 406-E11	454

[a] DDTC, diethyldithiocarbamate.

very low, so that the matrix remaining in solution might be considered relatively simple. Because of this, method development can often be focused towards fast analysis and high sample throughput.[466,467] Nevertheless, STPF conditions and ZBC frequently have to be used.[423,456–465] In any case, the absence of interferences should be checked, for example, by recovery studies using reference materials. In the meantime, reference materials have been produced for which, in addition to the certified total concentration, information is also provided on the fraction that can be leached by aqua regia, for example, soil samples NIST SRM-2709[468] and SRM-2711,[469] Bureau Communautaire de Référence (BCR) CRM 141R,[470] 142R[471] and 143R[472] and sewage sludge samples BCR CRM 144R,[473] 145R[474] and 146R.[475]

4.2.2.4 Direct Analysis of Solid Samples and Slurries

As has already been mentioned, the graphite furnace can be used as a thermochemical reactor, performing in situ digestion. Procedures have been developed that allow for the determination of the total concentration of an element, either by direct solids analysis[476,477] or by slurry sampling.[478,479] In addition to the benefit of not having to perform a digestion (especially when the digestion is really problematic, e.g. for coal), the major reasons for the application of these techniques are the much lower sample requirement and the increased sensitivity. The application of the STPF concept and ZBC are quasi prerequisites for accurate analyses,[476,480,481] because the matrix often has a substantial influence on the appearance time and the signal profile.[482] A number of authors have attempted to simplify the introduction of the solid dust samples by punching small disks from the filter and analyzing directly.[481,483] The precision of this procedure is nevertheless poorer than when the filter is homogenized in a mill.[484]

In contrast to direct solids analysis, the analysis of slurries is more flexible, and precision and trueness are better for the analysis of slurries in comparison with solids,[485,486] especially when they are homogenized by an ultrasonic probe directly mounted to the autosampler of the GFAAS instrument.[487–491] Further improvements, such as a reduction of the background attenuation, can be obtained by in situ ashing with air or oxygen[492,493] or the addition of hydrogen to the purge gas.[494] Aqueous calibration solutions can often be employed in combination with matrix modification. Special attention has to be paid to particle size and density effects, which might call for particle size reduction, which could then reduce the benefit of reduced sample preparation owing

to the absence of a predigestion. For the same reason, the atomization of slurry samples by FAAS, which has been performed with sample introduction by FI,[450,495,496] has not attracted great attention owing to the restriction to very fine particles or analytes that can be easily extracted into the aqueous phase during the preparation of the suspension.

4.2.3 Selective Extraction of Individual Constituents and Bonding Forms

The determination of the total concentrations of analytes cannot give the right answer to many environmental questions, such as evaluation of the exposure of plants and animals to pollutants, evaluation of the fertility of agricultural soil or risk assessment for a waste dump site. Rather than the total concentrations of elements, the part which is bioavailable to plants and animals, the part which is leachable and mobile and thus can move away from the site and reach the aquifier and so on is of interest for such studies. For this type of element speciation, leaching procedures using a variety of differing reagents, either in a single step or in a sequential extraction scheme, have been used successfully for decades. The choice of extractant will depend not only on the element in question but also on the soil type, the crop or animal species, the weather and the technique for determination. The list of extractants which have been used is correspondingly long and sequential extraction schemes using a set of extractants are also numerous, varying between three and nine steps for differentiation. Descriptions and comparisons of such procedures can be found in review articles which have been published recently for soils and sediments by Rauret,[497] Jones[498] and Ure et al.[499] and for waste materials by Van der Sloot.[500] The method developed by Tessier et al.[501] has been applied to all the materials discussed here and is designed to differentiate between five fractions:

1. *Exchangeable fraction*. Trace metals adsorbed at the surface of particles, which can be desorbed by simply changing the ionic composition.
2. *Carbonate fraction*. Trace metals associated with carbonates, which are susceptible to pH changes.
3. *Fraction bound to Fe/Mn oxides*. Iron and manganese oxides are present as nodules, concretions, cement between particles or as a coating on particles. These oxides are excellent scavengers for trace metals and are thermodynamically unstable under anoxic conditions.
4. *Fraction bound to organic matter*. Trace metals bound to organic matter, such as organisms, detritus, coatings on mineral particles, etc. through complexation, peptization or bioaccumulation. These metals can be released by degradation of the organic matter under oxidizing conditions.
5. *Residual fraction*. The residual solid, having resisted the removal of the previous fractions, contains trace metals in the crystal lattice structure. It is believed that normal environmental conditions do not release these metals.

In sequential extraction, the bioavailability of metals is meant to decrease with each step of the scheme, but it is generally recognized that most extraction schemes are less than perfect. Few extractants can be relied on to release elements solely from a particular phase[502–504] and redistribution between phases can occur during the sequential procedure.[505,506] Also, the results will depend on the thermal pretreatment of samples.[507] Also, such operational defined methods do not help any fundamental understanding of the chemistry involved but offer only empirical guidance.[508]

Despite these limitations, they are often specific enough to provide the information necessary for making diagnostic or managerial decisions. However, the different extractants and the numerous extraction schemes used significantly hinder the comparability of results between different studies. In order to overcome such problems, harmonized procedures have been developed, such as those under the auspices of the BCR,[509–511] for the single extraction with ethylenediaminetetraacetic acid (EDTA) or acetic acid and a sequential extraction scheme using three steps, which is given in Table 10. The use of microwave heating for speeding up the extraction procedure[512] can also lead to improved reproducibility. In addition, reference materials are now available for which not only the total element content but also extractable portions are certified.[513–516]

For the determination of the element by AAS, it is of no great consequence whether the sample material is a soil, a sediment, a sludge or a waste material. Since

Table 10 BCR sequential extraction scheme

Extraction	Extractant	(Nominal) phase extracted
Step 1	0.11 mol L^{-1} acetic acid	Exchangeable
Step 2	0.1 mol L^{-1} $NH_2OH{\cdot}HCl$, pH 2	Reducible, Fe/Mn oxide
Step 3	8.8 mol L^{-1} H_2O_2, then 1 mol L^{-1} CH_3COONH_4, pH 2	Oxidizable – organic and sulfide

only relatively small element concentrations are extracted during the leaching, especially with weak extractants, FAAS is only sufficiently sensitive for a few elements, such as Al, Ca, Co, Cu, Fe, K, Li, Mg, Mn, Na, Sr, Zn.[517–522] This situation might be different for airborne particulates, for which the extractable concentration of some more metals (e.g. Cd, Cr, Ni, Pb) might be sufficient for their determination by FAAS.[365,523–525] However, in many cases for elements such as Ag, As, Cd, Cr, Mo, Ni, Pb, Se, Sb, Sn, Te, Tl, V, it is usually necessary to apply GFAAS[519,520,526–531] or other more sensitive techniques. Owing to the considerably lower total salt concentration, the matrix influences are far less pronounced than with a complete digestion, at least for those extractants that do not add significantly to the total salt concentration.

4.2.4 Speciation Analysis in Soils, Sediments, Sludges, Dust and Other Solid Samples

The determination of redox species and organometallic compounds in solid materials, such as soils, sediments and sludges, is preceded by an extraction procedure, and in this respect is similar to the determination of bioavailable species. The determination of the individual species from the extract is hardly different from the analysis of water. In rare cases where FAAS is sensitive enough for speciation analysis, the separation procedure for the species is coupled with preconcentration, for example, for the determination of Cr(VI).[532–534] The use of GFAAS for speciation analysis has been reviewed by Das and Chakraborty.[303] As has already been pointed out, GFAAS is not a very suitable technique to be coupled with chromatographic separation since all attempts to run GFAAS in a continuous mode were unsuccessful,[535] and coupling between these two techniques[536] has to be done via either a fraction collector or a flow-through subsampling interface.[537] These interfaces require careful synchronization[538] and optimization of the flow rates and sampling intervals,[539] which significantly reduces its applicability. Other techniques, which can be operated continuously, such as vapor generation techniques (CVAAS, HGAAS) or plasma techniques, such as ICPMS, are much better suited.

For those cases where GFAAS has been used for speciation analysis of soils, sediments, sludges and dust samples, mostly nonchromatographic separation procedures have been used. These include the extraction of Cr(VI) in a weakly alkaline medium,[67,540–542] the extraction of tributyltin oxide with *n*-hexane–dichloromethane[543,544] or isooctane[545] and its back extraction with nitric acid.[543,544] The selective extraction of chelates has been applied for the species determination of As(III),[546] Sb(III)[547] and Cr(VI).[548]

The determination of Cr(VI) in welding fumes is one of the most important industrial hygiene examinations owing to the toxicity of this species.[362,549] The influence of the collecting procedure, the welding fumes themselves, the storage period and the analytical procedure have been investigated in detail.[550] While the Cr(VI) content of fiberglass filters did not appear to change over several weeks of storage, Rohling and Neidhart[551] found that during collection Cr(VI) is reduced by SO_2, which can lead to severe losses of Cr(VI), depending on the length of the collection period. Girard and Hubert[552] showed that the Cr(VI) can be quantitatively recovered from the filter medium by extraction with acetic acid–sodium acetate. Brescianini et al.[553] eliminated the interferences caused by large quantities of calcium, iron and sodium during the determination of chromium by GFAAS by separating the analyte on an ion exchanger.

Moreover, ion exchangers, chelating resins and other solid sorbents have been utilized in batch or column procedures to distinguish between different arsenic species such as As(III) and As(V),[554] Cr(III) and Cr(VI)[555] and organotin compounds.[556]

4.3 Biological Materials

Biological materials are investigated not only for environmental analysis, but also for reasons of biological, biochemical or biomedical analysis, toxicological, pharmaceutical, nutritional and clinical analysis, food analysis or biogeochemical analysis; the information sources available about sampling and analysis of such materials are correspondingly spread over a wide range of disciplines. For the purpose of environmental analysis, it is seldom the biological material itself which is the primary target of interest (as in toxicological or biomedical analysis), but its function as an indicator for the environmental compartment from which it was taken. In this function, biological materials are collected from different compartments of the environment. For the same reasons, other inorganic materials are collected, to gain information about the conditions of that particular compartment with respect to being part of a hostile biosphere or to learn about the exchange and fluxes of materials (pollutants) between different compartments or different parts of a compartment. With respect to biological materials, the primary concern is the entrance of pollutants into the food chain and the concentration of such pollutants by bioaccumulation. For plants and vegetable products, sources of pollutants are the soil on which they are grown, fertilizers, crop protection agents, insecticides and pesticides used and atmospheric precipitation, especially due to the proximity of roads or industrial installations. Animals (and humans) are influenced by the environmental conditions either directly (e.g. aquatic environment) or indirectly by

taking up pollutants (e.g. with their nutrition or drinking water) from that environment.

Those biological objects and systems which respond very sensitively to anthropogenic influences on the environment can be used as bioindicators for the detection of the presence of pollutants and biomonitoring can be used as a more quantitative method for the determination of the pollutants present. For example, low-level plants such as lichens and mosses accumulate large amounts of heavy metals, because their unprotected surfaces provide ion-exchange facilities which allow the effective adsorption of metals. The complexes then formed between the metals and the negatively charged organic groups are fairly stable. The accumulation of heavy metals on such plants is the basis for their use as bioindicators of atmospheric pollution. The problem with biological materials as samples for environmental analysis is biological variation, which hampers the assessment of baseline concentrations and the interpretation of analytical results.

The analysis of biological materials by AAS has a long history. While the reasons for analyzing biological materials are numerous, the different objectives are secondary for the selection of methods and techniques applied to the determination of elements in these materials by AAS. Review articles have been published by Slavin on the use of FAAS[557] and GFAAS[558] for the analysis of biological materials in general, by Hanlon[559] on plant analysis, by Rains[560] on the subject of foodstuffs analysis, by Pritchard and Lee[561] on agricultural samples and by Hoenig and Guns[48] on environmental and biological samples. Apart from review articles on single elements already mentioned (see section 4), numerous other minerals and trace elements are treated in the monographs *Quantitative Trace Analysis of Biological Materials* edited by McKenzie and Smythe,[562] *Trace Minerals in Foods* edited by Smith,[563] *Trace Element Analysis of Biological Specimens* edited by Herber[564] and *AAS in Occupational and Environmental Health Practice* written by Tsalev.[565] Markert gives an overview of plant analysis[566] and the use of bioindicators[567] and Kiceniuk and Ray treat the analysis of contaminants in edible aquatic resources.[568] Annual reviews on the determination of elements in biological materials appear in the *Journal of Analytical Atomic Spectrometry*.[569]

4.3.1 Sampling and Sample Pretreatment of Biological Materials

Again, an analyst should not waste time in investigating a laboratory sample whose history is not known in complete detail and is not documented. Sampling is of decisive significance for the accuracy of the analyses of biological materials. Some problems are common with the sampling of other sample materials, for example, selection of appropriate locations, techniques and designs, errors due to the limited numbers of samples and contamination due to the tools used. However, the main problems are the high biological variability and biotic and abiotic influences on the availability of the sample material and on the reproducibility of its analysis. For example, such influences are as follows:

1. the exposure of the biological species and its behavior with respect to accumulation;
2. the time of sampling with respect to the season and to the phenological state of development of the biological species;
3. fluctuations or trends in the abundance or composition depending on age, gender or physiological state or morphological and genetic variability;
4. fluctuations between sampling locations with respect to edaphic or microclimate factors and exposure to emission;
5. errors due to a selective sampling procedure, favoring individuals or groups, having special characteristics.

For the sampling of plant materials, this means that one has to decide which parts of the plant to sample (roots, leaves, needles, etc.), their location with respect to the soil (distance from the ground) and their exposure (free-standing plant, plant from a forest ecosystem).[570] Furthermore, the time of exposure depends on the age of that particular sample, which must be known (e.g. to create comparable results when sampling tree needles of different ages).[571] Depending on the questions to be answered by the investigation, one has to decide whether external contamination of the plant material by soil and precipitation has to be removed before analysis or not.[572,573] If it has to be removed, the cleaning procedure must be designed to remove only the external contamination, and to avoid leaching the plant components.[574] If external contaminants should not be removed, the sampling procedure has to assure the retention of those components.

When sampling biological materials of animal origin, a practical method of capture, not prone to contamination, and in accordance with ethical rules, is a prerequisite for using that species for environmental analysis. Depending on the type of sample (body fluid, soft tissue, hard tissue) and whether it can be collected without killing the animal (e.g. bird feathers, egg shells, body fluids), one has to account for changes in element distributions due to stress or postmortem changes (autolysis, etc.).[575] Contamination risks are especially high when internal organs have to be taken by dissection or when blood samples have to be analyzed.

These and other sampling and presampling factors cannot be discussed in detail here. Comprehensive information on this subject has been published by Jones and Case,[576] Keith[577] and Markert.[578] In the laboratory, the sample must be homogenized, conserved and typically stored.[579] Naturally, all precautions to prevent contamination from tools, containers, the laboratory atmosphere and losses due to volatilization or adsorption must be scrupulously observed. For the homogenization of plant and animal tissue samples, cutting and mixing tools that have stainless-steel parts are often used. Contamination can be expected from such tools, especially for Fe, Cr and Ni.[580]

4.3.2 Digestion Procedures

Plants and biological tissues are usually decomposed for the determination of total element concentrations by AAS techniques, although they can be determined also by direct techniques using solid-sample introduction or slurry sampling. The main reason for using routine decomposition techniques is concerns about the homogeneity of sample masses as small as a few micrograms. In addition, the samples often have to be prepared as powders and such pretreatment may take as long as a fast decomposition technique.

For the decomposition of various biological materials, a wide selection of methods have been developed, including dry ashing, wet digestion, pressure digestion and MWD. The selection of an appropriate digestion procedure depends on the analyte, the sample matrix and the method of determination. In general, atomic spectrometric techniques do have a much higher tolerance against residual carbon after the digestion than other instrumental techniques such as electrochemical methods, since residual matrix components can be destroyed during atomization. The amount of residual carbon which can be tolerated by different AAS techniques decreases in the order FAAS > GFAAS $\gg$ HGAAS/CVAAS. Digestion solutions, which are clear and free from particles in general, fulfill the requirements for FAAS.

In the 1960s and 1970s, dry ashing was widely used, since relatively large sample aliquots can be ashed (up to 20 g) and taken up in a minimum volume of acids. In this way, many trace elements could be determined by FAAS, which was the only technique available at that time. Dry ashing can be performed directly or with the addition of ashing aids such as magnesium nitrate or small amounts of nitric acid and sulfuric acid, usually at 450–550 °C. Accurate temperature control, often not available with simple muffle furnaces, is a prerequisite for complete destruction of the organic material without loss of analytes.[581] The ash is then leached with dilute hydrochloric acid or nitric acid. Care is needed to make sure that losses due to siliceous ash residue or by adsorption on the wall of the crucible are avoided. The addition of hydrofluoric acid might be helpful to avoid such residues[582] while the choice of an adequate crucible material is of prime importance to avoid adsorption losses. Since the most important retention losses have been reported for silica and porcelain vessels, platinum vessels are generally recommended. Losses have been observed also for volatile elements, such as Hg, As, Se and Cd, but often can be circumvented by the addition of ashing aids. High blank values, which are difficult to control, at least when standard muffle furnaces are used instead of special furnaces (e.g. equipped with quartz walls), often limit the applicability for samples with low trace metal contents. Nowadays dry ashing is only applied sporadically, since other digestion procedures are faster and better.

Oxidative wet digestions are used far more frequently than dry ashing or fusions for subsequent analysis by FAAS or GFAAS. These can be performed in open vessels, with reflux condensation if required, or in closed containers under pressure (autoclaves). Open vessel digestions have a number of disadvantages, which should exclude them from the list of recommended procedures, especially (a) low sample throughput and (b) incomplete digestion due to low reaction temperatures, (c) high consumption of reagents creating high costs, large amounts of waste and environmental pollution by fumes, (d) high risk of contamination due to the amount of reagents and the exposure to the laboratory environment and (e) the possibility of analyte losses due to volatilization. In order to reach the necessary oxidation power with open-vessel digestions, strongly oxidizing, high-boiling acids such as perchloric acid, sulfuric acid and phosphoric acid are often used as digestants. These acids are more difficult to clean up than lower boiling acids and are thus more strongly contaminated. Further, the use of such acids cannot be recommended in combination with determination by GFAAS for many reasons: these acids (a) penetrate the graphite lattice and often remain in the tube after pyrolysis, leading to (b) reduction of the lifetime of the graphite tube and to (c) background interferences by molecular absorption. In the case of perchloric acid, volatile chlorides can be formed, leading to analyte loss during pyrolysis and/or atomization especially for main group III elements (aluminum, gallium, thallium).[583–585] Even in FAAS these acids create some problems, either by reducing the uptake rate of the nebulizer because of their high viscosity or by other interference effects.[586] By using low-boiling mineral acids, complete destruction of the organic material is not often possible by open digestion. However, it has frequently been shown that many elements can be extracted from biological materials, even with diluted mineral acid, without complete destruction of the organic material.[587] In any case, such methods

cannot be generalized and have to be verified for the matrix being investigated. In general, animal materials cause fewer problems than plant materials, and elements such as Ca, Cd, Cu, K, Mg, Mn, Na, Pb and Zn can be more easily extracted than Al, Cr, Fe, P and Si.

While the application of high-boiling acids for AAS is problematic, it is the oxidation power which is needed to decompose totally the complex organic matrix of some of the environmental samples. Of the mineral acids that are compatible with AAS (e.g. HNO_3, H_2O_2, HCl and HF), only the first two develop sufficient oxidation power but, because of their low boiling points, the oxidation power is not enough for complex matrix-containing substances, which are difficult to digest, such as fat. In order to raise the boiling point of these acids and therefore their oxidation power, the wet digestion procedure can be performed under pressure. There are many advantages of a pressure dissolution compared with open acid dissolution.[588] Since the pressurized decomposition vessel represents a closed system, the loss of volatile elements is avoided, in addition to the risk of contamination from the laboratory environment. Depending on the pressure which the system can withstand, either temperatures in the region of 200 °C (medium pressure, ≈80 bar) or >300 °C (high pressure, ≈130 bar) are possible. Under such harsh conditions, the total decomposition of complex matrices is possible, and organic materials can be decomposed with very little residual carbon remaining in the digest (<1%). The disadvantage of pressure digestion in autoclaves ('bombs') is the small amount of organic matter which can be treated. The special problem with biological materials is that large amounts of gaseous products (CO_2) are formed during the digestion. As a result, the maximum sample mass that can be loaded into such pressure vessels is limited to about 200–500 mg for a vessel volume of about 100 mL for medium-pressure systems and about 1 g for high-pressure systems. Using a medium-pressure system, operated at 170–180 °C, the optimum digestion time for biological materials with nitric acid is about 3 h.[589] For a high-pressure digestion system, the effective digestion time can often be reduced to about 1.5 h. About 2 mL of nitric acid are generally sufficient for a pure carbon content of 100 mg, independently of the type of biological sample. For determining the maximum sample mass, one has to consider that the carbon content of dried biological material varies between 35 and 50% for plant materials and between about 45 and 55% for animal materials with the exception of oils and fats that have carbon contents between 74 and 78%. Nitric acid alone is sufficient for complete digestion under high pressure for most elements and biological sample types.[589] Some samples (e.g. some plant samples, mussels) contain high amounts of silicate, requiring the addition of hydrofluoric acid. For more details, introductory papers and review articles on pressure digestion should be consulted.[588,590]

Since the end of the 1980s, these various digestion techniques have been increasingly replaced by microwave-assisted acid digestions which are frequently performed in closed containers and under low (up to 40 bar) to medium pressure (up to 80 bar).[408,591] The major advantages compared with conventional digestion techniques include the reduced time and reagent requirements, the lower blank values, the reduced risk of analyte losses, the possibility of automation and the ability to digest a number of samples at the same time. When comparing the time required for a conventional pressure digestion (CPD) and for a MWD, one has to consider that the digestion time is drastically reduced in a microwave system. This is shown in Table 11.

The most important difference is the fast heating for MWD. In addition to the time advantage for MWD, there is also an advantage with respect to the wear of materials. The digestion vessels in CPD are under heat and pressure stress for a much longer time than the vessels in MWD systems. Therefore, the vessels in CPD systems wear out earlier, and contamination due to sorption/desorption processes are more pronounced than in MWD systems.

The time gain with MWD is further reduced when the digestion cannot be performed in a single step. This is the case when either the gases produced during the digestion must be vented or reagents have to be added after the first step in order to complete the digestion. Especially under low-pressure conditions, the oxidation power of nitric acid is not sufficient for all types of material. Materials rich in fat are especially difficult to decompose[592] and often require the addition of additional oxidants such as hydrogen peroxide.[593,594] Stronger oxidants such as sulfuric acid and perchloric acid are (besides their incompatibility with GFAAS) also not very useful in MWD. Typically, they develop their oxidizing power at such high temperatures (above 250 °C) that the polymeric material often used for the vessels breaks down. When a single-step digestion is the target for method development, the method requires careful optimization

Table 11 Comparison of the time involved in MWD and CPD (in minutes)

Preparation step	MWD	CPD
Preparation of the digestion (weighing of the sample material, adding the acids, capping the vessels)	10	10
Digestion period (heating)	10–20	180–210
Cooling period	5–10	20
Preparation of the determination	5–10	5–10
Cleaning of vessels	5–15	10–20
Total time	35–65	225–270

with respect to the matrix. Chemometric techniques have been applied for this purpose.[595] State-of-the-art MWD systems having temperature and/or pressure sensors for each vessel require much less method development and optimization, since the digestion can be automatically operated under optimum conditions.[426,427] Some systems use quartz vessels that can be used at temperatures above 200 °C and allow pressures up to 80 bar.

In addition to these widely used digestion procedures a number of techniques have been proposed that have not come into general use, but can occasionally be of interest as comparative techniques or for a special combination of analytes and matrices. A comparison of such techniques with respect to their characteristics is given in Table 12. Since FAAS and GFAAS methods do not require the highest digestion quality with respect to completeness of the destruction of organic materials, even the incorporation of MWDs into flow systems has been successfully performed for some biological materials. A review of such methods was presented by Burguera and Burguera.[596] Solubilization of materials with tetramethylammonium hydroxide (TMAH) has been used successfully, sometimes under microwave assistance,[597] especially in combination with speciation. Other less frequently used techniques are based on combustion in a stream of oxygen in a closed system[592,598] or on intense infrared (IR) irradiation. Details of these and other techniques can be found in treatises and review papers on sample digestion.[599,600]

4.3.3 Methods for Flame Atomic Absorption Spectrometry

In general, digestion of solid material is always combined with dilution. Under normal conditions, when using acid digestion, 200–500 mg of biological material are usually decomposed in about 5 mL of acid, the digest being then diluted to 10–20 mL. Hence the dilution factor is about 40 for such decomposition, if not higher. Following such dilution and remembering that a technique should only be applied in its optimum working range, FAAS is suitable without reservation only for the direct determination of major components such as potassium, sodium, calcium and magnesium and minor components such as copper, iron and zinc. In some cases manganese can also be determined by FAAS in biological materials. Under given conditions it is also possible to determine aluminum, chromium, nickel and silicon. The use of the nitrous oxide–acetylene flame is a prerequisite for most of these elements to obtain correct results. Table 13 presents a number of recent applications.

For other trace elements in biological materials, the sensitivity of FAAS is generally not sufficient. For such cases, preconcentration has often been used in combination with FAAS, especially before 1980. Since today more sensitive direct methods, using for example GFAAS, are available, such preconcentration methods cannot be recommended any longer.

These classical preconcentration techniques take on a fully new dimension when they are performed automatically and on-line in a closed FI system. The most often used methods of preconcentration with such FI/FAAS

Table 12 Digestion methods for biological materials[a]

Method	Contamination	Completeness	Throughput	Costs	Comment
Dry ashing (450–550 °C)	+++	++/+++	++	+	Usually less applicable for low contents and high precision
Combustion	++/+	+++	++	++	Low sample throughput
Open acid digestion, automated system	++/+ ++	++ ++	+++ ++++	++ ++	Medium to high sample throughput
Open microwave-assisted	++	++	++++	++	High sample throughput
Pressure digestion PTFE < 200 °C	++/+	++	++	++	Digestion quality mostly sufficient (at least for AAS)
Microwave-assisted pressure digestion, <200 °C	++/+	++/+	+++/++++	++	Digestion quality not always sufficient
Microwave-assisted pressure digestion, <250 °C, quartz vessel	+	++/+++	++	++	Digestion quality mostly sufficient (at least for AAS)
High-pressure digestion, >300 °C	+	++++	++	++++	Optimum digestion quality but costly
UV-photolysis	+	++	++	++	Restricted applicability, but possibility of on-line digestion in FI systems

[a] +, Small; ++, medium; +++, high; ++++, very high.

Table 13 Selected publications on the analysis of biological materials by FAAS

Analyte	Sample material	Remarks	Ref.
Ca, Cr, Cu, Fe, Mg, Mn, Zn	Biological reference materials	Comparison with ICPOES	601
Ca, Fe, K, Mg, Zn	Biological reference materials	Comparison of CPD and MWD	602

techniques for the analysis of biological materials are sorbent extraction on packed microcolumns,[615–618] precipitation/coprecipitation[619,620] and sorption in knotted reactors.[621,622] More important than high enrichment factors is the high rate of sample throughput that can be achieved with these on-line techniques, making them very suitable for FAAS. Enrichment factors of 16–40 with a sample throughput of 120–180 h^{-1}[622,623] appear to be much more sensible than enrichment factors of 90–180 at a sample throughput of only 13 h^{-1}.[624] In addition, if the enrichment time is too long, the susceptibility to interferences and the risk of errors increase, such as the breakthrough of the column.

4.3.4 Methods for Graphite Furnace Atomic Absorption Spectrometry

Digests of biological materials contain about 5–50 mg of the original matrix per milliliter of solution. Since about 50% of the biological matrix is hydrocarbons, which were oxidized and removed as gases during the digestion, the remaining matrix is of the order of 2–30 mg mL^{-1}. This salt content is much higher than for fresh water and the highest concentrations may reach those of seawater. This means that for those cases where the analyte concentration is low, as in seawater, the analysis of biological materials approaches the complexity of seawater analysis. For this reason, the direct analysis of biological materials has greatly benefited from the development of the STPF concept and the instrumentation associated with it. It is accepted nowadays that accurate results can be obtained for the direct analysis of many biological materials by strictly applying this concept and by excluding all forms of contamination. For example, As, Cd, Cu, Fe, Pb, Sb, Se and Zn have been determined by using platform atomization and applying Pd–Mg as modifier and B, Cr, Mn by using Mg as a modifier. The vast amount of literature in this area has been reviewed in the form of a monograph by Tsalev[565] covering the publications up to 1993 and by Welz and Sperling[2] covering publications until 1997.

The number of publications on extraction techniques has decreased markedly owing to the clear advantage of the direct determination of trace elements by GFAAS with respect to simplicity, sample throughput and accuracy. The application of such techniques can be restricted to those cases where the concentration of the element is not sufficiently high for a direct determination. Preconcentration is often required for noble metals such as gold,[625,626] palladium and platinum,[598,627–630] but also for a number of other trace elements such as beryllium,[631] bismuth,[632] cobalt[633,634] and nickel[635] under certain conditions.

Although biological materials are relatively easily dissolved or digested, direct solids analysis has frequently been described (about150 publications during 1975–99). Problems with atomization interferences and background correction, reported in early publications since 1975, have been largely overcome by ZBC and the STPF concept. Introduction of air or oxygen during pyrolysis allows for in situ ashing and helps to avoid carbon build-up in the graphite furnace. Intercomparison studies have shown that direct solid analysis of biological materials is often able to produce accurate results, even when using only samples masses in the range 1–5 mg. When samples are properly homogenized, relative standard deviations in the range <10–20% are typical. When 5–10 subsamples are analyzed by direct solid sampling, confidence intervals for the mean result are in general within about ±10% as precise as the determination of a digest with 2–3 subsamples.

Of special interest is solid sampling for the distribution analysis of biological structures (e.g. birds feathers, human hair, special regions in organs), very small samples (e.g. insects), or for the investigation of the homogeneity

of samples. A disadvantage of solid sampling GFAAS is that not all modern furnaces allow for the introduction of solid samples and often special equipment is needed.

This and other disadvantages can be overcome by the use of suspensions of powdered samples (slurry) in a solvent such as water or dilute acid. Using an automated slurry sampler incorporating an ultrasonic probe for homogenization just prior to dispensing the sample volume into the furnace, fully automated analysis is possible with characteristics very similar to those in solution analysis. Homogenization by ultrasonic agitation is very effective, so that practically all types of biological samples can be suspended in dilute nitric acid with the addition of Triton X-100 as a wetting agent. By using a slightly wider sampler capillary (0.8 mm i.d. instead of the standard 0.4 mm i.d.), particles $< 600\,\mu m$ can be dispensed without major problems. Table 14 gives an overview of elements determined in biological materials by either solid- or slurry-sampling GFAAS.

A complete overview of these techniques can be found in a monograph edited by Kurfürst.[478]

4.3.5 Methods of Speciation Analysis for Biological Materials

Being part of the biosphere, living organisms take part in the environmental cycling of elements. Owing to the metabolism of living organisms, trace elements can be present in biological materials in a large variety of chemical forms. To identify the physiologically active forms, to store and transport of species and to find sensitive indices of the status of trace elements are the main purposes of most environmental investigations into speciation in biological systems. In general, in the investigation of toxic effects, the speciation of small molecules is of concern (e.g. methylmercury), whereas in the investigation of biological functions the determination of large molecules has priority (e.g. vitamin B_{12}).

As in other areas of speciation analysis, the methods of sample collection, pretreatment and storage of biological materials for speciation studies are critical. Not only must a representative sample be collected without contamination, but also the distribution and integrity of the chemical species has to be maintained. Changes in parameters such as temperature, ionic strength, pH, pE, oxygen level, irradiation with UV light, to which the sample is exposed during and after sampling, can influence the speciation of elements. In general, it is essential to choose those analytical conditions which do not differ markedly from those found in the original system, in order to minimize such influences.

Most of the speciation studies on biological materials have been carried out with wet tissue, which is either extracted as fresh material or has previously been dissected and rapidly frozen. Extraction can be performed by blending the sample as a paste or slurry with the selected solvent or solvent mixtures[637] using an Ultra Turrax homogenizer or ultrasonication. Other techniques, such as supercritical fluid extraction (SFE) or microwave-assisted leaching have been applied for this purpose. Using selective extraction procedures for separation, 'first-order speciation' is sometimes possible, especially when the number of species present is limited or when a group parameter is sufficient for the characterization. The most often performed speciation analysis of biological materials is the determination of methylmercury. However, this determination is only rarely done by using GFAAS. The most frequently described technique is extraction of methylmercury chloride or methylmercury bromide from acidic solution with toluene (e.g. fish tissue). The extract can then be analyzed directly by GFAAS after addition of dithizone or thiosulfate acting as a modifier.[638]

The determination of inorganic and organic arsenic compounds is also of great interest. A review of methods for arsenic speciation in environmental and biological samples has been published by IUPAC.[59] Again, since the GFAAS technique cannot be easily coupled with separation techniques such as HPLC, arsenic speciation analysis by using GFAAS has not found wide application. By using extraction with KI–toluene, the more toxic species As(III), As(V), monomethylarsenic

Table 14 Biological matrices and elements investigated by solid-sampling and slurry-sampling GFAAS [information from the literature[2,478,636]]

Matrix	Elements determined by solid-sampling GFAAS	Elements determined by slurry-sampling GFAAS
Animal tissues	Cd, Cs, Hg, Ni, Pb	B, Cd, Cr, Cu, Fe, Mn, Ni, Pb, Se, Si, Sn
Biological reference materials	Ag, As, Cd, Co, Cr, Cs, Cu, Fe, Hg, Mn, Mo, Rb, Se, Tl, Zn	Al, As, B, Ca, Cd, Co, Cr, Cu, Fe, Hg, Mg, Mn, Mo, Ni, Pb, Se, Sn, Zn
Human materials (hair, nails)	Ag, Al, As, Ba, Cd, Co, Cr, Cu, Fe, Hg, La, Mg, Mn, Ni, Pb, Pt, Se, Zn	Al, Ag, B, Cd, Co, Cr, Mn, Ni, Pb
Plant tissues	Cd, Co, Cu, Fe, Mg, Ni, Pb, Tl	Cd, Co, Cr, Cu, Fe, Mn, Ni, Pb, Tl, Zn
Marine and aquatic samples	As, Cr, Fe, Mn	As, Cd, Co, Cr, Cu, Mn, Ni, Pb, Se

acid and dimethylarsenic acid can be separated from the nontoxic arsenobetaine. Determining arsenic in the extract by GFAAS then gives the total toxic arsenic concentration.[639,640]

Organotin compounds are of interest because of their toxicity. This applies in particular to tributyltin oxide, which is used as an antifouling paint. The separation of this compound from mussels and other marine organisms starts with the extraction from the homogenized tissue mixed with hydrochloric acid by using an organic solvent such as *n*-hexane. Mono- and dibutyltin compounds can be removed with dilute sodium hydroxide solution, and the tributyltin oxide is back extracted in nitric acid. The tin concentration in the extract is determined by GFAAS.[543,544,641,642] Another tin compound of interest is the pesticide tricyclohexyltin hydroxide (Cyhexatin). Residues in apples can be determined directly by GFAAS after extraction with chloroform.[643]

Bioavailable chromium has been determined in cereal products, vegetables and oil seeds by extraction with ethanol and determination by GFAAS after a digestion of the extract.[644] When the extraction of the material alone is not selective for the species, a separation technique such as liquid chromatography (LC) has to follow. Of the LC techniques available, fractionation according to size [SEC or fast protein liquid chromatography (FPLC)] has been most frequently used.

For selenium speciation, the determination of the organic compounds and the distinction between inorganic selenite and selenate are of interest. Ion chromatography has been applied to separate selenite and selenate, and FAAS and GFAAS were used for on-line detection, depending on the required sensitivity for the analysis of feedstuffs and selenium additives in animal feeds.[645] A greater number of inorganic and organic selenium species can be separated by coupling FPLC with GFAAS via an ultralow volume fraction collector. By using this approach for the determination of selenium species in plant tissues, a sensitivity was obtained that is comparable to that obtained by LC/ICPMS.[646,647] Again, extraction of such Se species from the biological tissues is a critical step.[648]

Chromium speciation, which is of great importance because of the high toxicity of Cr(VI), has not been widely applied to biological materials. Metal-free HPLC equipment and fast procedures are a prerequirement for obtaining undisturbed speciation; FPLC was successfully used to separate different Cr complexes extracted from cabbage xylem.[649] Positively charged chromium(III) species and kinetically labile complexes are not retained on the column, while the relatively stable chromium(III)–EDTA and –oxalate complexes and chromium(V) are retained and separated. Determination of chromium in the individual fractions was performed off-line by GFAAS.

For the separation of various lead species in biological materials, fractionated wash procedures using organic solvents and acids of varying strengths have been applied.[650,651] The investigation of roots, foliage and other plant components, and the dissection of leaves into subcellular fractions with the corresponding compartmentalization of the lead content, have been described.[651] In many cases GFAAS is used as the determination technique for the sum determination of volatile lead, that is, tetraalkyllead compounds in marine organisms.[650]

Metallothioneins and other high molecular weight species are often determined by LC separation with various AAS detectors. A review of coupled techniques used for such analysis has been presented by Lobinski et al.[652] The major interest is in cadmium,[653–661] but other elements such as copper,[655,658,661–663] zinc,[658,661] lead,[655] magnesium,[663] nickel, silver[661] and thallium[660] are also determined. It is of particular interest to determine to which protein the metal is bound; gel filtration and gel permeation chromatography are especially suitable for separating various metal-binding proteins. The determination of the metal concentrations in the eluate is carried out either by on-line coupling with FAAS or by GFAAS. Likewise for this application, the difficulty of coupling HPLC with AAS detectors is apparent. On-line coupling with FAAS is possible when the nebulizer aspiration rate is reduced to about $2\,mL\,min^{-1}$, but the sensitivity is relatively poor.[654,658,664] Sensitivity can be improved by using high-efficiency nebulizers for interfacing, such as the thermospray nebulizer.[653,655,663] GFAAS offers the required sensitivity but it can only be applied off-line[656,657] by using a fraction collector or quasi-on-line by a flow-through interface,[537] both with limitations with respect to resolution and versatility as already mentioned (see section 4.1.5).

Other techniques which have been used in combination with AAS detection are ultrafiltration,[665,666] ultracentrifugation[667,668] and supercritical fluid chromatography (SFC).[659]

ABBREVIATIONS AND ACRONYMS

AA	Atomic Absorption
AAS	Atomic Absorption Spectrometry
APDC	Ammonium Pyrrolidine Dithiocarbamate
ASV	Anodic Stripping Voltammetry
BCR	Bureau Communautaire de Référence
BOC	Baseline Offset Correction
CPD	Conventional Pressure Digestion
CPG	Controlled-pore Glass
CRM	Certified Reference Material
CVAAS	Cold Vapor Atomic Absorption Spectrometry

DDDC	Diethylammonium Diethyl-dithiocarbamate
DDTC	Diethyldithiocarbamate
DQO	Data Quality Objectives
EDL	Electrodeless Discharge Lamp
EDTA	Ethylenediaminetetraacetic acid

An overview is given on the most important applications of flow-injection (FI) systems developed for environmental materials, highlighting their main basic components and modes. Also, the article systematically describes the different FI manifolds coupled to spectrometric or electrochemical (EQ) detectors used for the determination of analyte species to offer diverse solutions in the analysis of various samples.

1 INTRODUCTION

The rapid growth in agriculture and industrial activity has resulted in chemical pollution. Industrial waste water, toxic metals, toxic organic substances, sewage sludge and soil waste materials have been discharged into the environment. The complexity of the real samples and the diversity of analytes typically encountered in environmental studies hampers the direct analysis of key components by use of a specific detection technique. To supply required data rapidly, efficiently, with the demanded accuracy and precision and with the least human attention, it would be an advantage to count on reliable and easily automatable systems.

Undoubtedly, any FI system can be considered to have a certain degree of automation mainly of the preliminary operations of the analytical process. On the other hand, it can be readily adapted to virtually every type of analytical problem, it allows direct control by the researcher and can be interfaced with a variety of possible configurations with different optical or EQ instruments typically used in routine laboratories.[1] In this respect, FI systems have proven useful for handling contaminated complex samples and for direct pretreatment of solids and liquids with harsh chemical matrices. For these types of analytes/samples the primary advantage of FI is economic. A secondary advantage is the ease of development or refinement of method.

2 HISTORY

From the birth of FI important applications have been developed for agricultural, metallurgical, food, biological and environmental materials. Ruzicka et al. initiated the FI-spectrophotometric and potentiometric approach for the determination of phosphorus[2] and total nitrogen content in plant materials.[3] The same research team demonstrated for the first time the feasibility of using ion-selective electrodes for the determination of potassium, sodium and nitrate in soil extracts.[4] The Brazilian group of Piracicaba initiated the FI-turbidimetric[5] method (for the determination of sulfate in natural waters and plant digests) and atomic absorption spectrometry (AAS)[6] (for the determination of calcium, magnesium and potassium in plant materials) approaches. The first two papers dealing with the determination of air pollutants (chlorine, bromine and SO_2) were published by Mottola et al.[7,8] based on photometric detection. Since these pioneering works were published, many books[1,9–13] and reviews[14–18] have provided an overview of the developments of FI interfaced with different kinds of detectors, highlighting the different applications in the various fields, including environmental analysis. Undoubtedly, the largest effort for the development of FI techniques for environmental analysis has been focused in the use of spectrophotometric, atomic spectrometry (AS) and some EQ detectors. The control of pollutants in waters (cationic, anionic and organic pollutants), sludges and sediments (metallic species) has received most of the

Encyclopedia of Analytical Chemistry

attention, while the determination of air pollutants has been more restricted.

3 DEVELOPING METHODS FOR SAMPLE PREPARATION

The organic matter often present in environmental samples, in most cases interferes with the subsequent instrumental measurement. This serious problem can be eliminated through processes capable of converting the organic constituents into inorganic, which are free of this type of interference effect or by removing the analyte from the interfering matrix through any conventional separation technique. Transformation of the analyte into a form that can be analyzed by a specific measurement technique often requires unpleasant, tedious and time-consuming procedures such as dilution, separation, dissolution or digestion. Depending on the type of matrix, the analyte and its expected concentration in the sample and the technique to be used for measurement, one pretreatment procedure or various are to be followed. These appear to be the reason for the rather late development of FI digestion procedures followed by on-line detection of the analyte. Ultraviolet (UV), ultrasonic and microwave (MW) radiation emerged in the analytical field to dramatically improve the digestion process. Additionally, the development of on-line decomposition systems proved to be simple; they are relatively safe to use, provide a decrease in the blank values, reduce the contamination risk, are applicable to samples of different nature and are completely fit for automation. The automated procedures enable on-line coupling of the pretreatment procedures to powerful determination methods such as spectrophotometry, turbidimetry, flame atomic absorption spectrometry (FAAS), hydride generation (HG) and electrothermal atomic absorption spectrometry (ETAAS), inductively coupled plasma/atomic emission spectrometry (ICP/AES), inductively coupled plasma/mass spectrometry (ICP/MS), fluorimetry and EQ methods or to hybrid techniques such as high-pressure liquid chromatography/atomic absorption spectrometry (HPLC/AAS) or HPLC/ICP/MS, which widened the application fields to speciation studies.[19]

4 MANIFOLD CONSIDERATIONS

The complete FI system would contain a sampler, the FI unit, a detector and a recording device that is capable of sample identification and evaluation of the detector signal in terms of analyte concentration. In a typical FI procedure, the entire dynamic process may take place in open tubular reactors and, therefore, a certain degree of mixing between the injectate and reagent streams is necessary before the reaction zone reaches the detector. Thus, it is necessary to emphasize the applicability of different injection modes, pumping and manifold design, which are important considerations in the field of environmental analysis. Despite the intrinsic characteristics of a given detection technique, it does not always meet the demand for specificity, sensitivity and/or selectivity for environmental analysis. The feasibility of employing in-line sample preparation further enhances the utility of FI techniques for the analysis of many samples of environmental origin, and improves the performance of the detector. In this way, (a) the reagent/analyte chemistry can be carried out under the required conditions, (b) interferents can be minimized or eliminated resulting in selectivity enhancements, (c) preconcentration of the analyte allows for lower detection limits (DLs), (d) the analyte can be placed into some detectable form and (e) speciation studies can be carried on.

The final design of a FI system is dependent on the particular requirements of the user and on the conditions defined by the method. Since sample dispersion is being used to affect specific functions, including sample dilution, mixing, reaction, preconcentration steps, etc., it should be controlled as meticulously as possible. In seeking to exploit the chemistry fully, it is desirable that manifold modifications can be made rapidly and easily to save time. In particular, the interface of the FI manifold with the detector unit must be described in detail to allow its use for routine purposes by other researchers.

5 MANIFOLD DESIGNS WITH SPECTROMETRIC DETECTORS

5.1 Spectrophotometry

The simplicity of the reactions and the ease of adaptation to continuously flowing systems enhanced the popularity of FI spectrophotometric methods for the determination of many environmentally important species, especially in water samples. The first applications were carried out with the aim of demonstrating the principles of FI techniques. Thus a number of FI manifolds have been adapted to well-known spectrophotometric methods to determine a number of anionic[20–22] and cationic (calcium, iron, aluminum, lead, manganese, mercury, etc.)[22] as well as organic species.[19–23] With few exceptions, the manifolds are single line and permit the control of the pH and color formation, dilution of samples or preconcentration of the analyte with enhanced sensitivity and without loss of reproducibility.

Most of the spectrophotometric methods developed for the determination of sulfate are based on the removal of barium by sulfate, from its complexes with different color indicators followed by the measurement of the free ligand: methylthymol blue,[24] dimethylsulphonazo-III[25–27] or chloranilate.[28] Barium chromate and barium chloranilate[29] reaction columns were used as components of FI manifolds for the determination of microamounts of sulfate in sea and surface water and in rainwater samples, respectively. Other methods, indirectly determined sulfate by measuring the absorbance of thiocyanate[30] or of the $FeSO_4^+$ ion.[31] The catalytic effect of sulfate on the reaction between zirconyl ions and methylthymol blue was also used for the indirect determination of sulfate.[32] DLs in the range 0.1 to 0.6 mg L^{-1} with relative standard deviation (RSD) below 4% but low sample throughput (up to 30 samples per hour) and narrow working range (up to 14 mg L^{-1}) have been achieved, although in most of these cases, removal of interfering cations by ion-exchange was necessary.

The majority of the FI procedures developed for the determination of different forms of organic and dissolved phosphorus so far are based on the complexation of orthophosphate with acidic molybdate, although strong interferences from silicates have been reported. Most of the published methods require a preliminary digestion step to convert all the phosphorus compounds present in the sample to orthophosphate. The early procedures involve hydrolysis and thermal oxidation in long digestion coils (10 m) with consequent lengthy residence times at high temperatures and elevated pressure necessary to mineralize the organic and condensed phosphates. Less drastic conditions have been needed for a heated reactor containing platinum wire as catalyst in the presence of persulfate.[33] Speciation of dissolved phosphorus in environmental samples was possible by gel-filtration in a FI manifold.[34] UV photooxidation has been successfully used to perform in-line determination of organic phosphorus in natural waters with good sensitivity and precision.[35] Different materials and designs of photoreactors were tested in the development of the method. Teflon photoreactors have been preferred – some of their advantages being: robustness, low cost, suitability for field applications and ease of manufacture. Samples in the range 0.1 to 4 mg P L^{-1} can be analyzed at rates of 72 to 50 samples h^{-1}, respectively, with a DL of 0.01 mg L^{-1}.

An on-line MW digestion of wastewater was carried out by Haswell et al.[36] The MW pretreatment of samples with the inorganic enzyme pyrophosphatase ensured the determination of total phosphate, as straight-chain polyphosphates and ring metaphosphates, probably present in the samples, were all converted to orthophosphate. The system design allowed all the operations, including sample injection, digestion, de-bubbling, cooling, pressure control, mixing with reagents and signal measurement to be carried out on-line in about 2 min, compared to 25 min when using traditional digestion methods. A similar, low-cost and robust FI on-line MW-induced sample digestion for total phosphorus in natural waters and wastewater has also been described in the literature.[37] A 6 m poly(tetrafluoroethylene) (PTFE) flow-through reactor located in a domestic MW oven was used to produce the optimal oxidation and hydrolysis of the organic and condensed species suspected to be present in the real samples, with the aid of peroxodisulfate dissolved in perchloric acid. The orthophosphate formed was also detected as phosphomolybdenum blue after on-line filtration of the digest.

Free cyanide has been spectrophotometrically determined in FI systems by slowly (over 30 min) developing the color with a buffered chloramine-T solution used as carrier, or by injecting, in a reversed-mode system, pyridine/barbituric acid reagent into the buffered chloramine-T solution.[38] For total cyanide determination, which includes complexed cyanide, the procedure must be preceded by a tedious distillation which, if incorporated in the manifold might result in a rather complicated system with low sampling frequency. However, the combination of a fast reaction, based on the rapid formation of an unstable red intermediate product with isonicotinic acid/3-methyl-1-phenyl-2-pyrazolin-5-one, with the on-line generation and separation of hydrogen cyanide resulted in a successful system for preconcentration and sampling of total cyanide.[39] A sampling frequency of 40 h^{-1}, a DL of 6 μg L^{-1} and a preconcentration factor of 3.5 for a 2 mL sample have been achieved.

FI spectrophotometric methods developed so far for the determination of free chlorine in such samples are based on the formation of colored complexes with: *o*-tolidine (yellow),[40] *N*,*N*-diethyl-*p*-phenylene diamine in phosphate buffer (pink)[41] or 4,4′-tetramethyldiamino-thio-benzophenone (blue).[42] Only the latest method is sensitive enough (0.2–1.0 mg L^{-1}) to measure free chlorine in tap water.

Another anion very often determined in water samples is chloride. The most common procedure is based on the measurement of the red-colored complex between iron(III) and thiocyanate. The amount of chloride is proportional to the absorbance measured at 480 nm. Single-line manifolds permitted the application of a simple methodology to different types of samples (surface, ground, rain or seawater and the expansion of the working range by using the stream splitting principle[43] or performing on-line dilution.[44] However, the sampling frequency is rather slow (up to 120 h^{-1}) and the precision poor (1–8%) taking into account that the sample volume was large (up to 400 μL). Better sensitivity has been achieved (0.01–10 mg L^{-1}) for the determination

of chloride in air and water, based on the Fe(II)/Hg-tripyridyl-s-triazine flow system.[45]

Although nitrogen is well known as an essential element to life, some of its compounds (urea, ammonia, nitrite, nitrate, amines, etc.) could be hazardous to health if present in high concentrations in water supplies owing to their toxicity or carcinogenity. Simultaneous determination of nitrate and nitrite is possible by controlling two consecutive steps: reduction of nitrate to nitrite; the efficiency of this reaction depends on the metal used, the conditioning of the column and the pH and diazotation, which will depend on the reagents used. Zinc(II), copper(II) or copperized cadmium columns have been used in the reduction step.[46] The nitrite is diazotized with sulfanilamide and the product coupled to *N*-(1-naphthyl)ethylenediammonium dichloride to form an azo dye which is measured at 520 nm.[47] A more sensitive method used *p*-aminoacetophenone for diazotization, coupled the product with *m*-phenylenediamine at pH 1.5–3.0 and measured the absorbance at 460 nm.[48] Many modifications and adaptations of the original procedure have been published, all aimed to increase sensitivity, column lifetime, sampling rate and selectivity.

The commonly used methods for ammonia determination are based on the Nessler and Berthelot reaction in which ammonium ion is transformed into ammonia, separated through gas-permeable membranes and the gas absorbed on-line in a specific reagent and the color intensity measured at 640–800 nm.[49]

There are several spectrophotometric methods for the determination of boron in environmental samples that require a prior separation step owing to lack of sensitivity.[22] One of the most sensitive methods applied for the determination of boron in this type of sample is based on the formation of a complex with azomethine-H using ultrasonic leaching or a time-based injector[50] to avoid time-consuming sample treatment and reagent consumption, respectively.

Calcium in natural waters, soil extracts and plant digests has been spectrophotometrically determined in a FI system using the principle of merging zones.[51] Glyoxal bis (2-hydroxyanil), known as a sensitive and selective reagent for calcium, was used as the color-forming reagent. Interference effects from co-existing elements in the matrixes studied were minimized by the addition of triethanolamine and potassium cyanide to the carrier stream. A sampling rate of 180 determinations h^{-1} with a RSD of less than 1% have been accomplished. Chlorphosphonazo-III in hydrochloric acid (pH 2.2) was used as a chromogenic reagent for the determination of calcium in seawater in a FI system with a sampling throughput of 200 to 250 injections h^{-1} and insignificant effects from other alkaline-earth elements.[52]

An indirect FI spectrophotometric method based on the exchange reaction between calcium and the zinc complex of ethylene glycol-bis(2-aminoethylether)tetraacetic acid in the presence of 4-(2-pyridylazo)resorcinol has been described.[53] The sampling rate was 80 samples h^{-1} and the results for pond and tap water samples were in good agreement with those obtained by FAAS.

Dissolved chromium concentrations in natural waters is below 1 μg L^{-1} and its determination is dependent on the preconcentration method used and changes between species [Cr(VI)/Cr(III)] during sampling and/or storage. Ion-exchange coupled on-line with the standard method based on Cr(VI) color formation with 1,5-diphenylcarbazide is an example of a successful application to seawater samples.[21]

A simple FI set-up based on the absorbance of the orange-red iron(II)-1,10-phenanthroline complex at 512 nm allowed the determination of iron(II) and total iron in a large number of waters and plant digests. However, FI systems need serious optimization procedures to be followed in terms of sensitivity, linearity, sampling rate, etc. Natural computation techniques, using jointly the neural network and genetic algorithms have been applied in the modeling and optimization of a FI manifold for the colorimetric determination of iron(III) in water samples.[54] Thiocyanate was used as a color developing reagent. A comparison with AAS showed the high quality of the results. However, discrimination between Fe(II) and Fe(III) species has certain relevance in aquatic environments where they are active in many redox processes. The Fe(III)−SCN complex was selectively retained on a flow cell packed with an exchange resin while the oxidation of Fe(II) to Fe(III) took place in the loop of a previous valve.[55] The method presents a determination limit of 80 μg L^{-1}, a linear range of 80–500 μg L^{-1} for Fe(II) + Fe(III) and a precision of 5%.

Several automated FI systems have been developed for the photometric determination of lead after on-line column preconcentration, based on its property of forming a colored complex with 2-pyridylazo resorcinol,[22] and with 5, 10, 15, 20-tetra(4-*N*-sulfoethylpyridinium)porphyrin[56] or the extraction with dicyclohexyl-18-crown-6 into chloroform from acidic medium and addition of dithizone as chromogenic agent.[22]

Eriochrome Cyanine R in the presence of cationic surfactants proved to be a very sensitive photometric reagent for the determination of aluminum in natural waters.[57] A strict on-line control of the pH and interference effects from some concomitant species permitted the determination of aluminum in the range 0.8 to 4 mg L^{-1} with a precision RSD of 0.7% at 1 mg L^{-1} level and a DL of 1 μg L^{-1}.

Maximova et al. optimized an on-line preconcentration of some heavy metals (Pb, Co, Mn and Fe) on a capillary

column with a hydrophobic inner surface followed by MW sample processing for photometric detection in swamp water.[58] The procedure eliminates the noise caused by the organic matrix and allows the immobilization of the photometric reagents on the sorption column.

In order to avoid costly instrumentation such as ICP/AES or AAS, a fast, automated and inexpensive screening-test for recognizing heavy-metal contamination of drinking, surface and wastewater was implemented.[59] The test was based on the reaction of Cd, Co, Cu, Ni, Pb and Zn with dithizone at pH 6 followed by the on-line extraction of the complexes in carbon tetrachloride and photometric measurement at 500 nm.

In many environmental studies related to water quality monitoring the analysis of a large number of samples for chemical oxygen demand (COD) is often required. However, certain steps of the reactions involved prior to the spectrophotometric determination of such species are very slow. MW irradiation has been used to accelerate the oxidation of the organic matter with a potassium dichromate–sulfuric acid mixture for COD determination in natural waters.[60] This reaction takes about 2 h in a conventional system and only a few minutes in a flow-injection microwave (FI/MW) irradiated on-line arrangement. The determinations were performed up to 100 mg L^{-1} with a precision RSD of 2.12% at 40 mg L^{-1} and a DL of 1.5 mg L^{-1}.

On-line MW treatment of water samples proved successful for the reduction of urea to ammonium ions, which on reaction with NaOH release gaseous ammonia. The gas diffuses through a hydrophobic membrane and causes a pH change in a bromothymol blue indicator stream which is colorimetrically measured at 635 nm.[61] Calibration was linear up to 45 μmol L^{-1}, with a DL of 2.4 μmol L^{-1} (ten times higher than in the conventional method), a precision RSD (4%, $n = 4$) and a sampling rate, including sample preparation, of 14 min per sample. Although the sensitivity was worse, there are many advantages (better precision, better recoveries, rapid analysis and ease of automation) over the batch procedures.

A similar procedure, based on color change of bromothymol blue was used for the indirect determination of trimethylamine oxide in seawater at micromolar levels.[62] The analyte was converted to the volatile trimethylamine through a titanium-mediated deoxygenating reaction; the method features a wide linear operating range (0–200 μmol L^{-1}) and high sensitivity with cheaper instrumentation and lower maintenance.

5.2 Turbidimetry

The turbidimetric detection of barium sulfate is almost universally used for the determination of sulfate ions in waters. The sample containing sulfate is injected in a carrier stream of barium chloride and allowed to mix in the manifold in order to form a uniform suspension. The turbidity is measured at 420 nm, but the accuracy and precision strongly depend on the crystalline form and size distribution of the precipitate particles in the suspension. Therefore, strict control of the experimental conditions must be undertaken at any time; this perfectly suits the FI concept because every standard and sample can be treated under exactly the same conditions. There are some problems associated with this procedure, namely the stability of the suspension, accumulation of precipitate on the tubing lines as well as the presence of suspended organic matter or colored components in the sample. Polyvinyl alcohol[63] and gelatin[64] have been used to stabilize the barium sulfate to improve the precision. The unfavorable build-up of precipitates on the transfer lines as well as their tendency to settle in the flow cell led to blocking of the manifold. Addition of hydrochloric acid to the carrier stream prevents the formation of barium carbonate, chromate, phosphate or oxalate and the alternating injection of an alkaline buffer–ethylene diamine tetraacetic acid (EDTA) solution redissolves the accumulated barium sulfate precipitate and keeps the system clean.[65,66] The use of pH gradients and alkaline EDTA provided a stable suspension, which obviates the use of protective colloids. EDTA was also found useful for reducing interferences from metal ions.[67] In order to avoid interferences from turbid samples, Van Staden incorporated in the manifold a prevalve filtration accessory consisting of a packed activated carbon tube[68] or an active carbon filter paper.[69] The incorporation of an anion exchange resin in a FI manifold permitted the preconcentration of sulfate for its sensitive turbidimetric determination in water.[70]

A silver nitrate turbidimetric procedure has been applied to the determination of chloride in river water in a single-line flow system.[71] The turbidity of silver chloride suspensions formed in nitric acid is measured at 440 nm in the range 0 to 14 mg L^{-1} with a sampling rate of only 15 h^{-1}.

5.3 Atomic Spectrometry

Initial reports dealt with the use of the FI system as a mere alternative to manual introduction for FAAS. In such systems, the noise problems associated with the air bubbles in segmented sample insertion systems are eliminated, the analyst can use sample volumes in the microlitre range per measurement, and the sample flow rate is optimized to allow higher atomization with a net increase in sample analysis throughput. Olsen et al.[72] determined cadmium, copper, lead and zinc in polluted seawater at the part per million level at a

rate of 180–250 samples per hour; however, the sampling frequency depended on the preconcentration required. They developed an on-line FI preconcentration method using a microcolumn of Chelex-100 resin, allowing the determination of lead at concentrations as low as $10\,\mu g\,L^{-1}$ and $1\,\mu g\,L^{-1}$ for cadmium and zinc.

Martínez-Jimémez et al.[73] have developed a continuous precipitation and filtration flow system coupled on-line with the atomic absorption spectrometer. This technique allows the quantitative separation and preconcentration (by a factor of 700) of trace amounts of lead from tap water samples. Ammonia is used as a precipitating reagent and no collector was required. Several calibration graphs suited to the degree of enrichment were proposed for the determination of lead(II) in the range $1.2–1500\,\mu g\,L^{-1}$.

On-line coprecipitation–preconcentration systems can also greatly improve the DLs down to 0.23, 3.2 and $1.4\,\mu g\,L^{-1}$ for determination of metal species such as cadmium, lead and nickel, respectively, in various water samples and soils. The analytes are precipitated and collected on the inner wall of a knotted reactor with diethyldithiocarbamate-copper(II) and eluted with isobutyl methyl ketone.[74]

The advantages of FI solvent extraction coupled with AAS include high preconcentration factors, improved nebulization efficiency, reduced reagent consumption and the reduction of laboratory waste.[75] Gallego et al.[76] reported the indirect determination of anionic surfactants with an automatic continuous liquid–liquid extractor. The method involves the formation of the detergent-[1,10-phenanthroline-copper(II)] ion pair and extraction into methyl isobutyl ketone. The overall concentration can be determined indirectly by measurement of copper present in the organic layer by AAS. A phase separator fitted with a PTFE porous membrane was specially designed for the determination of detergents in the concentration range $0.1–5.0\,\mu g\,mL^{-1}$.

Ma et al.[77] described a FI on-line sorbent extraction system to determine cadmium, copper and lead in digest solutions of environmental samples using octadecyl functional groups (C_{18}) bonded silica gel as sorbent with diethylammonium-*N*,*N*-diethyldithiocarbamate or ammonium diethyldithiophosphate as complexing agent and methanol as eluent. DLs were 0.8, 1.4 and $10.0\,\mu g\,L^{-1}$ respectively for cadmium, copper and lead. These elements were determined in coal fly ash, calcareous loam soil and lake and estuarine sediments.

Interesting work presented by Bysouth et al.[78] used masking agents in the determination of lead in tap water by FAAS with FI preconcentration. The selectivity of immobilized 8-hydroxyquinoline for lead was improved by the use of masking agents during preconcentration, prior to its determination. Interference by iron, copper, aluminum and zinc is suppressed by including triethanolamine, thiourea, fluoride, acetylacetone or cyanide in the buffer as masking agents. On the other hand, Sperling et al.[79] determined chromium(III) and chromium(VI) in fresh water samples using on-line preconcentration with selective adsorption on activated alumina. Linear calibration for both species was established over the concentration range $10–200\,\mu g\,L^{-1}$ with DLs of 1.0 and $0.8\,\mu g\,L^{-1}$ for Cr(III) and Cr(VI) respectively.

The research team of Perkin-Elmer at Uberlingen has introduced some routine applications of on-line ion-exchange preconcentration systems for AS.[12] In particular, enrichment factors from 25 to 31 were obtained for copper, cadmium and lead from natural and sea water samples by FI coupled with AAS. Conical ion-exchange columns were found to be superior to uniform diameter columns in reducing dispersion during elution so that higher enrichment factors could be achieved using smaller sample volumes (1.6 mL per determination). The system can be easily also adaptable to an ICP spectrometric system.

FI sample introduction for ETAAS systems is less straightforward than FAAS or hydride generation atomic absorption spectrometry (HGAAS) owing to the discontinuity of ETAAS operation, this obviously being the cause of the slower development of the related techniques.[16] Historically, the main obstacles for efficiently and harmoniously combining FI on-line with ETAAS have been overcome by the research groups of the Department of Applied Research of Perkin-Elmer in Uberlingen and Mérida, Venezuela.[16,80] FI and ETAAS by on-line column preconcentration of metal species (such as: As, Pb, Cd, Co, Cu, Fe, Ni and Zn) from natural and seawater samples, has provided further impetus to the development in this field. Various sample introduction modes have been proposed by different workers. The conventional off-line mode is performed using pipettes for the deposition of the concentrate into the furnace after its pretreatment and collection in small vials. With on-line systems, the concentrates are dispensed automatically into the furnace by a pump via a sampling probe. FI also proved to be an efficient interface to ETAAS for: (1) sample deposition in the furnace by hydride sequestration, thermospray and high pressure nebulization; (2) selective sorbent extraction.[81]

Without any question, ICP at its current stage is the analytical technique that provides the most adequate simultaneous multielement analysis capacity. ICP allows the simultaneous assay of several elements at major, minor, trace and ultratrace levels without changing any experimental parameter in aqueous or organic solvents. However, the formation of polyatomic ions (particularly below $m/z = 80$) can cause serious interferences. Such

species can be introduced via precursor atoms in atmospheric gases, with the sample matrix or impurities in the argon support gas, and cause a systematic error. The first applications of FI/ICP can be traced in the review published by Christian and Ruzica in 1987.[14] Up to then, FI was used as an adjunct of conventional ICP instruments, which had bulky nebulizers. Therefore, FI systems are coupled to ICP or to ICP/MS for: (1) the on-line removal of matrix interferences;[82,83] (2) trace enrichment of analytes;[84] (3) on-line dilution[85] and (4) on-line sample digestion procedures.[86] In this context, trace metals in seawater,[82,87] sewage sludge,[86] waste water[88] and natural waters[88] have been determined with good precision and accuracy. The introduction of samples by capillary gas chromatography allowed the speciation and determination (down to $0.1\,ng\,L^{-1}$) of organotin compounds in river-water samples.[89]

Tsalev et al. have initiated the on-line MW sample pretreatment for the determination of Hg in water.[90] A reaction coil and a ballast-load coil are placed and oriented vertically within the cavity and chimney of a focused MW oven in a manner that provides a reliable long-term operation with increased reaction and irradiation times. Samples are mixed ''in batch'' with an appropriate oxidation reagent and loaded on an autosampler. Thereafter, all further operations are performed automatically within 90–402 s (depending on the sample volume and the instrument program used for a given determination). When the amalgamation accessory was used, a PTFE filter holder with a PTFE micropore membrane filter was placed between the gas–liquid separator and the quartz absorption cell to avoid aerosol droplets entering the amalgamation accessory. The limits of detection were 0.01 and $0.2\,\mu g\,L^{-1}$ for mercury, with and without amalgamation, respectively.

A technical note reports on the evaluation of a Perkin-Elmer flow-injection mercury system (FIMS) for the determination of Hg in sewage sludge, sediment and soil samples.[91] The DLs were as low as $5\,\mu g\,L^{-1}$ for sample volumes of 500 µL and RSD of 2% ($n = 3$) at $10\,\mu g\,L^{-1}$ Hg level. The same approach has been successfully tested for the determination of total mercury in environmental samples using MW digestion coupled to FIMS.[92]

A similar system was described by Lamble and Hill[93] for the determination of total mercury in environmental solid samples. The slurried samples were injected into a carrier of hydrochloric acid and brominated mixture before passing through the coil situated in the MW cavity. After mixing with hydroxylammonium chloride to remove excess bromine, mercury was determined in an on-line generation system. Each sample was processed in 50 s with a DL of $13\,ng\,L^{-1}$.

Morales-Rubio et al.[94] have described a two-line system for the determination of mercury in environmental materials (sewage sludge, polluted farmland soil and lake sediment) using on-line MW digestion and atomic fluorescence spectrometry (AFS) as detector. The acidified slurry samples (400 µL) were injected and carried through the PTFE digestion coil (4 m) located inside the oven (at 10% power level) for 50 s and through an ice/water bath. The reductant stream merged with the digest and mixed in a reduction coil before entry to the gas liquid separator. This system allowed accurate determination of mercury in certified environmental reference materials with a precision ranging between 0.5 and 1.5% RSD, a DL of $0.09\,ng\,g^{-1}$ and a throughput of 15 samples per hour.

Another interesting approach has been developed for the determination of total arsenic in geothermal water samples.[95] An appropriate volume of sample (0.1–2.0 mL) mixed with acids (H_2SO_4 and HNO_3) and an oxidizing agent ($K_2S_2O_8$) is subjected to MW heating. The cooled digest was mixed with a prereductant (KI and ascorbic acid) and sodium borohydride to form volatile arsine which was detected by FAAS in a quartz cell. The method allowed the determination of total arsenic with a DL of 0.2 ng of arsenic, a precision RSD of 2.5–4.5% and recovery values in the range 101–102%.

López-Gozálvez et al.[96] have described an on-line HPLC/MW oxidation-HGAAS four channel system for the selective determination of arsenite, arsenate, dimethylarsinate (DMA), monomethylarsonate (MMA), arsenobetaine (AsB) and arsenocholine (AsC) in environmental samples (mineral water, sewage water, harbor seawater, synthetic fish extract and sediment extract). Samples and multistandard solutions were injected into an anionic cartridge leading to a 100 µL sample loop, placed before an HPLC anionic column. Arsenite, arsenate, MMA and DMA were quantitatively retained in the anionic cartridge while AsB and AsC passed through it into the sample loop and separated in the chromatographic column. The column effluent mixed with the oxidizing solution flowed to the digestion coil in the oven for decomposition. The digest was cooled in an ice-bath and a T-junction was used to acidify the sample. In a second T-junction the digested sample was mixed with the reductant and the separated volatile arsine entered the quartz atomization cell. The anionic species can be separated and determined by removing the anionic cartridge from the system and introducing water instead of the oxidizing agent. After optimization of the chromatographic and MW-oxidation parameters, the RSD was 3–5% with DLs between 0.3 and 0.9 ng for all species (for 100 µL sample volume) and conversion efficiency close to 100% in all cases.

Le et al.[97] also speciated arsenic except that they used a dual system to avoid removal of the cartridge during the procedure. Comparable resolution was obtained by using HPLC-separation/MW-digestion with HGAAS or

ICP/MS detection. Complete separation of five arsenicals was achieved on a reversed-phase C_{18} column by using sodium heptanesulfonate as ion pair reagent and the DLs were for example $10\,\mu g\,L^{-1}$ for arsenite, DMA and AsB, $15\,\mu g\,L^{-1}$ for MMA and $20\,\mu g\,L^{-1}$ for arsenate.

An automatable and on-line cryogenic trapping system and MW heating was used for the determination and speciation of arsenic in aqueous samples by FI/HGAAS using sodium tetrahydroborate as reductor.[98] The separation of the species was based on a pH selective procedure: arsine from As(III) alone was generated in the presence of citric acid while nitric acid was used to generate the corresponding arsines from total inorganic arsenic, MMA and DMA. These were cryogenically trapped in a PTFE coil knotted and sealed inside another wider diameter tube located in the oven and through which liquid nitrogen was suctioned by negative pressure. Based on their different dielectric constants, the arsines were selectively liberated by using a heating cycle of MW radiation with volatilization times of 90, 180 and 235 s for dimethylarsine, monomethylarsine and arsine, respectively. The DLs were in the range 20 to 60 ng As for 10 mL sample volume, with the possibility of improving it by increasing sample size or running several consecutive reactions.

5.4 Luminescence

The first applications of FI coupled with chemiluminescence (CL) detection were reviewed by Burguera et al. in 1982.[99] Up to then, some metal species, tertiary amines, hydrogen peroxide and sulfite[100] were the species of environmental interest which were determined in natural waters. This initial trend has almost been followed up to date, but using different CL reactions, e.g. (1) the determination of tertiary amines in water and seawater over the range 1×10^{-5}–$1 \times 10^{-2}\,mol\,L^{-1}$ based on the oxidation of the analyte by sodium hypochlorite in presence of Rhodamine B as a sensitizer;[101] (2) the determination of aqueous ozone for potable water treatment;[102] (3) the determination of a nonionic surfactant in aqueous environmental samples;[103] (4) the determination of ultratrace concentrations of nitrite in water;[104] (5) the simultaneous determination of nitrate and nitrite in water by gas-phase CL.[105] One interesting application of FI is the in situ shipboard determination of species such as hydrogen peroxide,[106] copper and manganese using CL reactions.[107,108]

The analytical signals are dramatically affected by environmental conditions such as ionic strength, pH and interferents which can be stabilized in a FI system. The advantage of using FI for fluorescence-based measurements is that reproducibility can be significantly improved.[109] FI sample processing has been used for the determination of: 0–$10^{-5}\,mol\,L^{-1}$ total primary amines in seawater,[110] 0.2–300 $ng\,mL^{-1}$ copper(II) in natural waters;[111] 10^{-8}–$10^{-4}\,mol\,L^{-1}$ of residual peroxides in water;[112,113] and $\mu mol\,L^{-1}$ levels of sulfur species (sulfite, sulfide and methanethiol) in fogwaters[114] with good reproducibility, precision and rapidity using the *o*-phthalaldehyde/mercapto-ethanol, 2,2′-dipyridylketone hydrazone/hydrogen peroxide, *p*-hydroxyphenylacetate/peroxide/peroxidase and *N*-acridinylmaleimide/*N*,*N*-dimethylformamide reactions, respectively.

6 MANIFOLD DESIGNS WITH ELECTROCHEMICAL DETECTORS

The use of EQ methods in environmental analysis depends on the availability of instrumentation, trained personnel and practical procedures for complex matrixes. They are suitable for on-line field applications although EQ detection suffers from memory effects and electrostatic interferences. The design of flow-through EQ detectors for on-line couplings needs special consideration. Some novel sensors have been tried, including wall-coated (or open) tubular, packed bed (or porous) tubular, wire, cascade, wall-jet and thin layer designs. They monitor anionic species such as chloride, bromide, cyanide, nitrate and ammonium and to a lesser extent toxic metals, such as Pb, Hg, Cd, Cu, Zn and Ni, which substantially contribute to the pollution of land and water, and are readily determined by spectroscopic methods.

6.1 Amperometry

An amperometric flow-through detector was used for the determination of cyanide in different kinds of surface and groundwaters[115] by injecting the sample into an alkaline electrolytic carrier stream with good precision (2%) and high sampling frequency ($100\,h^{-1}$).

Arsenic was determined in contaminated soil samples by a novel technique based on gas diffusion through porous membranes.[116] Arsine generated in a donor stream of sodium borohydride passes quickly across a membrane into an acceptor stream of sulfuric acid, and the resulting solution is carried to a flow-through amperometric cell equipped with a dual gold electrode and Ag/AgCl as reference electrode. The detector provided enhanced selectivity, high sensitivity and low DL and affords the possibility of the development of field instrumentation for on-site determinations. A closed loop FI system was used for the determination of sulfur dioxide in air samples.[117] The manifold permitted the direct intercalation of air samples into a carrier solution containing the complex Fe(III)-1,10-phenanthroline as a regenerable chemical form. The extent of reduction of the complex to ferroin at the gas/liquid interface was

amperometrically monitored with an Ag/AgCl–carbon-paste electrode system. The composition and mode of preparation of the paste was found to considerably affect the performance of the system. The analyte was determined in the range 0.3–14.0 ppm (v/v) with RSD of about 3% at a rate of 25 samples per hour.

6.2 Ion-selective Electrodes

A home-made coated tubular solid-state chloride selective electrode was used by Van Staden to determine chloride up to 5000 mg L^{-1} with a precision of less than 1.7%.[118] The drawback of this procedure was the strong interference from mercury(II) ions. A similar approach was manufactured for the determination of inorganic bromide in soil in the range 1–5000 mg L^{-1}, at a rate of 80 samples per hour and with a standard deviation (SD) of 1.6%.[119]

Okumoto et al. interfaced a flow system with a gas-diffusion separator and a cyanide-selective electrode to screen wastes from metal plating processes.[120] They claimed a DL of 0.1 mg cyanide L^{-1} and a sampling frequency of 40 h^{-1}.

Improved DLs, compared to spectrophotometric methods, have been reported for the potentiometric determination of ammonium in seawater using a liquid-membrane ammonium-sensitive electrode[121] or a gas diffusion/dialyser unit.[35] On-line preconcentration on ion-exchange microcolumns and incorporation of gas-diffusion units proved successful but the final choice will depend on the particular analytical requirement.

6.3 Voltammetry

Voltammetric techniques, in particular absorptive cathodic stripping voltammetry are suitable for trace metal determination and speciation as they combine high sensitivity with speciation capabilities. Their combination with FI techniques facilitates in situ monitoring of various species in environmental samples.[122] For this purpose, a flow-through cell (4 μL) mounted in an automated voltammetric system monitored traces of cobalt in uncontaminated seawater.[123] A hanging mercury drop was used as electrode, while the chloride present in the seawater was the counter-ion for the Ag/AgCl reference electrode. The cell was combined with on-line UV digestion, on-line de-oxygenation and on-line standard addition for on-board determination of cobalt distribution in coastal waters.

Traces of metals can also be determined using chemically modified electrodes designed to enable both, preconcentration (binding) and surface interaction for subsequent quantification of the analyte accumulated on the surface. Carbon-paste electrodes for instance, are simple to prepare and have an easily adjustable fresh surface, which is generated in a reproducible manner. Such an electrode, modified with 1,2-bismethyl(2-aminocyclopentene-carbohydride)ethane was incorporated in a flow system for the preconcentration and determination of copper in water.[124] As little as 1.4×10^{-6} mol L^{-1} of Cu(II) can be determined in water with a precision of 2.9% for a preconcentration time of 4 min. Cu, Pb, Cd and Hg were determined in seawater, speciated as total particulate, particulate sorbed to inorganic matter, total dissolved and labile by differential pulse anodic stripping voltammetry.[125] The total-particulate-containing filters were MW digested and the organic matter in water samples was destroyed by UV photolysis. The elements in the filtered water were on-line pre-concentrated on a Chelamine microcolumn, eluted and determined by the EQ method and also by FAAS (Cu, Pb and Cd) or cold vapor atomic absorption spectrometry (CVAAS) (Hg) for quality control (QC).

7 DETERMINATION OF POLLUTANTS IN ENVIRONMENTAL SAMPLES

The main development in FI environmental analysis have been highlighted in the following reviews:

1982 Water pollutants.[99]
1985 Cations, anions, COD, halogens, sulfur dioxide, organic and other polluting species determination.[19,126]
1987 Anions determination.[11,14,20]
1988 Environmental samples.[1]
1989 Environmental samples.[9,10]
1990 Cations and anions and other polluting species determination.[15,127]
1991 Water quality monitoring.[21,128,132]
1994 Different pollutants in water.[23,129,130]
1995 Cations and anions determination in different kinds of samples.[12]
1996 Soil pollutants.[131]
1997 Different polluting species determination in different kinds of samples.[80]
1998 Different polluting species determination in different kinds of samples.[133]

8 THE PRESENT AND THE FUTURE

At present FI provides simple, handy, automable and versatile instrumentation which makes it suitable to meet the requirements of any laboratory wanting to make this type of analysis. The volume of papers involving the

analysis of water is substantial, and in a more restricted way the determination of different air and soil pollutants is well documented.

As realization spreads that the determination of the ''total'' concentration of an analyte is insufficient to yield an overall measure of toxicity, continued concern over environmental pollution will be reflected in the development and optimization of multielemental and speciation studies with imaginative FI setups. Analysis of biological materials as biomonitors of environmental pollution, airborne particulate, soils and waters will become of interest with on-line sample pretreatment, analyte separation from the matrix and preconcentration techniques to improve the sensitivity for the determination of individual species of the material under study.

ABBREVIATIONS AND ACRONYMS

AAS	Atomic Absorption Spectrometry
AFS	Atomic Fluorescence Spectrometry
AS	Atomic Spectrometry
AsB	Arsenobetaine
AsC	Arsenocholine
CL	Chemiluminescence
COD	Chemical Oxygen Demand
CVAAS	Cold Vapor Atomic Absorption Spectrometry
DL	Detection Limit
DMA	Dimethylarsinate
EDTA	Ethylene Diamine Tetraacetic Acid
EQ	Electrochemical
ETAAS	Electrothermal Atomic Absorption Spectrometry
FAAS	Flame Atomic Absorption Spectrometry
FI	Flow-injection
FIMS	Flow-injection Mercury System
FI/MW	Flow-injection Microwave
HG	Hydride Generation
HGAAS	Hydride Generation Atomic Absorption Spectrometry
HPLC/AAS	High-pressure Liquid Chromatography/Atomic Absorption Spectrometry
ICP/AES	Inductively Coupled Plasma/Atomic Emission Spectrometry
ICP/MS	Inductively Coupled Plasma/Mass Spectrometry
MMA	Monomethylarsonate
MW	Microwave
PTFE	Poly(tetrafluoroethylene)
QC	Quality Control
RSD	Relative Standard Deviation
SD	Standard Deviation
UV	Ultraviolet

Formaldehyde is a ubiquitous component of both the remote atmosphere and polluted urban atmospheres. Interest in ambient concentrations of formaldehyde derives both from concerns over health effects and from the primary role that formaldehyde plays in the tropospheric chemistry cycle. It is an important intermediate product occurring in all regions of the atmosphere, and arises from the oxidation of methane and other biogenic and anthropogenic hydrocarbons. In spite of the increasing interest in the levels and fate of formaldehyde in the environment, there is at present no simple method available for the determination of trace amounts (i.e. nanograms) of carbonyls in air, water, and other environmental samples. This article reviews all the available methods (qualitative and quantitative) for the analysis of formaldehyde in various matrices, including sampling of atmospheric formaldehyde. The various methods discussed include colorimetric, titrimetric, polarographic, and chromatographic methods. Fourier transform infrared spectroscopy (FTIR) and tunable diode laser absorption spectroscopy (TDLAS) have been reviewed, and fluorimetric methods of analysis have also been dealt with. The article includes a comparison of the various methods with respect to sensitivity, detection limits and interference.

1 INTRODUCTION

Formaldehyde (HCHO) is a ubiquitous component of both the remote atmosphere and polluted urban atmospheres.[1] This, together with the uniqueness of the chemistry it is involved in, make it a particularly important compound. Interest in ambient concentrations of formaldehyde derives both from concerns over health effects[2] and from the primary role that formaldehyde plays in the tropospheric chemistry cycle.[3] Formaldehyde is unique in that it acts as a funnel through which much of the carbon flux passes during the course of oxidation to CO and CO_2.[4]

In spite of the increasing interest in the levels and fate of aldehydes and other carbonyl compounds in the environment, there is at present no simple method available for the determination of trace amounts (i.e. nanograms) of carbonyls in air, water, and other environmental samples. In the field of atmospheric chemistry alone, measurements of parts per billion (ppb) levels of carbonyls in ambient air or simulated atmospheres (''smog chamber studies'') are critical to the development of a better understanding of hydrocarbon photochemistry, oxidant formation and removal processes including scavenging by precipitation, and atmospheric aerosols. Specifically, accurate formaldehyde measurements are important in constraining and validating photochemical models of the troposphere. Other important areas requiring measurement of trace levels of carbonyls in air include source and near-source sampling (engine exhausts, industrial emissions, etc.), and health related studies (e.g. indoor pollution, workplace environments etc.), all of which have important regulatory implications. In addition, formaldehyde is listed as a carcinogen or suspected carcinogen and its workplace exposure needs to be monitored.

Typical concentrations observed range from 0.5 ppb in remote areas to 75 ppb during severe air pollution episodes in urban areas.[5] In the late 1960s formaldehyde levels greater than 120 ppbv were observed by unambiguous spectroscopic techniques FTIR in polluted areas

near Los Angeles.[6] Between 1980 and 1985 the few data available show that the average concentrations in major cities were between 3 and 16 ppbv with maxima as high as 68 ppbv in Downey, California.[7] Average concentrations for the more remote Colorado mountains are around 1 ppbv during the summer and fall months,[8] while values between 50 and 500 pptv have been recorded for the Mauna Loa Observatory, Hawaii.[9,10]

About 24 million metric tons (Mt) of 37% formaldehyde solution are produced worldwide per year, of which 4.2 million Mt are in North America, 6.2 million Mt are in Europe and 6.3 million Mt are in Asia.[11] The end-uses of formaldehyde in the USA and in Europe are shown in Figure 1. The formaldehyde solution is incorporated into urea–formaldehyde and phenol–formaldehyde resins, which are widely used in industry for the production of foam insulation, particle board and plywood.[12] The particularly simple structure of formaldehyde results in extreme reactivity. Formaldehyde and ammonia yield methenamine, or hexamethylene tetramine, which is used as a urinary antiseptic. Nitration of methenamine gives the explosive cyclonite, also known as research development explosive (RDX). Formaldehyde reacts in the presence of $Ca(OH)_2$ to give pentaerythritol, the tetranitrate of which is the explosive pentaerythritol tetranitrate (PETN). The ready reaction of formaldehyde with protein leads to its use in the tanning industry and in treating various vegetable proteins to render them fibrous. The reactivity with proteins is also the basis for the use of formaldehyde as a disinfectant and embalming agent and as a soil sterilant.

Figure 1 End-uses of formaldehyde: (a) United States, 1997 total 4.2 million Mt, (b) Europe, 1997 total 6.2 million Mt.[11] MDI, methane diphenyl di-isocyanate.

Formaldehyde is an important intermediate product occurring in all regions of the atmosphere, and arises from the oxidation of methane and other biogenic and anthropogenic hydrocarbons. Formaldehyde serves both as a major source of the hydroperoxyl radical ($HO_2^{\bullet}$) and as a means of sequestering the hydroxyl radical ($^{\bullet}OH$) in the form of HO_2. Formaldehyde is also a major source of carbon monoxide in air masses not influenced by anthropogenic sources. In the troposphere, where the concentration of methane is considerably higher than that of non-methane hydrocarbons (NMHCs), methane becomes the dominant formaldehyde precursor. At the earth's surface, local sources of NMHCs also become important in producing formaldehyde. Formaldehyde is generated from the oxidation of biogenic hydrocarbons such as isoprene and the terpenes.[13–15] Formaldehyde is also anthropogenically generated directly from incomplete combustion processes and through secondary processes.[16] The predominant source of urban formaldehyde is believed to be the photooxidation of many hydrocarbons that are present in the atmosphere.[17] In rural areas of dense vegetation biogenic sources are often the predominant precursor. For example, isoprene oxidation (indicated by reactions with either OH or O_3) efficiently forms formaldehyde along with several other key atmospheric species.

Many foundries use furan resins as binding agents for sand, resulting in emissions of phenol, furfuryl alcohol and formaldehyde. In indoor environments, formaldehyde is emitted in substantial amounts as phenol and urea resins are incorporated into foam insulation, plywood and particle board. Growing concerns over the toxicity and the resultant properties of formaldehyde has created a significant demand for new methods to monitor exposures.

The use of titrimetric methods to measure formaldehyde concentrations is widespread for industrial hygiene applications and source measurements but the methods are not sensitive enough for ambient analysis. With colorimetric methods formaldehyde is converted into a chromogen by the addition of such compounds as chromotropic acid, pararosaniline, acetylacetone or 3-methyl-2-benzothiazolone hydrazone (MBTH) and the amount of chromogen is measured spectrophotometrically. They are among the earliest known of the refined versions,[18] are reasonably sensitive, have low detection limits and can be automated[19] but color development is relatively slow and sensitivity is limited.

Most of the present techniques for sampling atmospheric formaldehyde involve running a stream of atmospheric air through either a liquid or a solid sorbent. As the air passes through the sorbent it is scrubbed free of aldehydes. Liquid sorbents are normally placed in a small vessel called an impinger. Impingers must normally be

refrigerated if they are to be operated for long periods of time, otherwise the media will evaporate. The most common liquid medium for trapping formaldehyde is water. Solid sorbents alone do not have a high collection efficiency unless they are coated with a scavenger compound such as acidified 2,4-dinitrophenylhydrazine (DNPH), 2-hydroxymethylpiperidine or *N*-benzylene-ethanolamine. Low sampling rates of 1–1.5 L min^{-1} of air must be used, with typical sampling times of 20 min or several hours. Thus determinations of low concentrations of formaldehyde require rather long sampling times followed by rather slow laboratory analysis.

Chromatographic methods, including ion chromatography (IC) as formate, gas chromatography (GC), and high-performance liquid chromatography (HPLC), have been used for formaldehyde analysis. Direct analysis in urban air using GC has been less successful due to poor sensitivity.[20] However, derivatization of formaldehyde either in the sampling device or immediately after collection has improved stability of samples and allows quantitation of low levels of formaldehyde. GC of oxazolidine or the dinitrophenyl hydrazone derivative and especially HPLC of the DNPH derivative has been shown to provide adequate sensitivity.[21] Capillary GC has also been used

Table 1 Sensitivity and interferences of different quantitative methods

Method	Sensitivity	Interferences	Where used	Reference
Titrimetric methods				
Sodium sulfite	1.6×10^{-7} M	Aldehydes, methyl ketone	Field tests, air	Reynolds and Irwin[35]
Alkaline peroxide	–	Large amount of methanol		
Iodimetric	2.0×10^{-5} M	Organic impurities, ethyl alcohol, acetone	Small quantity of pure HCHO	Reynolds and Irwin[35]
Mercurimetric	–	Organic peroxides		
Potassium cyanide	–	Acetaldehyde (>5%) acetone (>5%)		
Hydroxylamine	3.3×10^{-6} M	Ferric salts decompose the reagent		Reynolds and Irwin[35]
Colorimetric methods				
Chromotropic acid	0.3×10^{-7} M	Acrolein, glyceraldehyde, β-hydroxy propionaldehyde, acetaldehyde		
MBTH	30 ppb	Aromatic amine azo dye, amino heterocycles	Air, rainwater, drinking water, wastewater	
Nash	0.05 ppb	Acetaldehyde, acrolein, propionaldehyde		
Pararosaniline	–			Miksch et al.[18]
Polarographic method	1.1 mg m^{-3}		Air, incomplete combustion	Septon and Ku[36]
Chromatographic methods				
Direct GC (FID detector)	0.3–0.8 ppm (in air)		HCHO in solution and high purity gas	Bombaugh and Bull[37]
GC using mass spectrophotometer	0.3 ppb		Air and rainwater	Yokouchi et al.[38]
HPLC, pre-column derivatization (DNPH)	2.5 g		Air and rainwater	Beasley et al.[39]
HPLC, post-column derivatization (MBTH)	4.8×10^{-8} M		Air and rainwater	Kim et al.[40]
IEC	–	Any substance that has a retention time coinciding with that of the formate	Air and rainwater	
FTIR spectroscopy	6 ppb		Air, vehicular emissions	Tuazon et al.[24]
Fluorimetric methods	120 ppt		Air	Lazrus et al.[28]
TDLAS	0.3 ppb		Air, tropospheric measurements	Mackay et al.[27]

FID, flame ionization detection; IEC, ion exchange chromatography.

to analyze formaldehyde derivatives.[22] Several of these methods suffer from stability problems and the need for expensive and specialized equipment for analysis. Faster real-time measurements are possible with spectroscopic methods. Spectroscopic techniques have included differential ultraviolet (UV) absorption,[23] FTIR.[24] and TDLAS.[25] These techniques generally employ long atmospheric paths or use multiple pass cells to attain adequate sensitivity. Sawicki et al.[26] studied a very large number of spectrometric methods for formaldehyde analysis and concluded that spectrofluorimetric determination with 2,4-pentanediene should be the method of choice when sensitivity, specificity and mild reaction conditions are desired.

Current techniques[8] employed in measuring ambient formaldehyde concentrations include TDLAS,[27] continuous scrubbing fluorimetric detection (CSFD),[28] DNPH derivatization techniques employing cartridges[29] and coils,[30] FTIR[31] and differential optical absorption spectroscopy (DOAS).[32] The first three classes of techniques were compared at a rural location in North Carolina in a study published by Kleindienst et al.[33] and again in the Los Angeles basin by Lawson et al.[34] (this study also included FTIR and DOAS measurements). In relatively clean rural air (5–15 ppbv) all methods appear to provide reasonably good agreement to within approximately 35%.[8] Table 1 shows different methods used for the estimation of formaldehyde for different matrices with respect to sensitivity and interferences.

2 PROPERTIES

2.1 Physical Properties

Formaldehyde (methanal) is a gas (bp $-21\,^{\circ}C$). Monomeric formaldehyde gas is characterized by a pungent odor and is extremely irritating to the mucous membrane of the eye, nose and throat even when present in concentrations as low as 20 ppm.[41] Formaldehyde is handled either as an aqueous solution (formalin) or as one of the solid polymers paraformaldehyde ($(HCHO)_2$) or trioxane ($(CH_2O)_3$). It is extremely soluble in water.

Monomeric formaldehyde is available commercially only in solutions stabilized with methanol. In most cases, these are aqueous solution with methanol contents ranging from 1 to 15%.

2.2 Chemical Properties

The chemical properties of formaldehyde are given in Table 2.

Table 2 Chemical properties of formaldehyde

Reaction conditions	Product
At high temperature	$CO + H_2$
Catalytic hydrogenation, $2H^+$	CH_3OH (Methyl alcohol)
$4NH_3$	$(CH_2)_6N_4 + 6H_2O$ (80%) Hexamethylene tetramine
$C_2H_5NH_2 + HCOOH$, $100\,^{\circ}C$	$C_2H_5NHCH_3 + CO_2 + H_2O$ Ethylmethylamine
H_2N-NH_2	$H_2C=N-NH_2H_2O$ Hydrazone
$C_6H_5NHNH_2$	$C_6H_5NHN=CH_2$ Phenyl hydrazones
NH_2OH	$OH_2=NOH$ Oxime
$H_2C=N-NH_2$	$H_2C=NN=CH_2$
$NHNH_2CONH-NH_2$	$NH_2NHCONHN=CH_2 + H_2O$ Semicarbazones
RSH	$H_2C(SR)_2 + H_2O$ Mercaptan
RMgX, H^+	RCH_2OH Alcohol
$LiAlH_4$	$CH_3OH + AlCl_3 + LiCl$ Methyl alcohol
PCl_5	$H_2CCl_2 + POCl_3$ Dichloromethane
NaOH	$HCO_2Na + CH_3OH$ Sodium formate
CH_3CHO, OH^-	CH_2OHCH_2CHO Glycolaldehyde
$C_6H_5COCH_3(CH_3)_2NH$	$C_6H_5COCH_2N(CH_3)_2$ Mannich base
C_6H_5OH	Bakelites
In dilute solution	$CH_2(OH)_2$ Methylene glycol
Evaporation (solid)	$CH_2OH(CH_2O)_nCH_2OH$ ($n = 6–50$) Paraformaldehyde
Conc. H_2SO_4	$(CH_2O)_n \cdot 2H_2O$ ($n > 100$) POMs
At room temperature	$(CH_2O)_3$ Trioxane
$Ca(OH)_2$	$C_6H_{12}O_6$ Formose

POM, polyoxymethylene.

3 METHODS OF MANUFACTURE

Formaldehyde is prepared industrially in three different ways. The first method involves the dehydrogenation of methanol. Methanol vapors are passed over a heated silver catalyst at 300 °C, as shown in Scheme 1.

$$CH_3OH \xrightarrow[300\,^{\circ}C]{Ag} HCHO + H_2O$$

Scheme 1

In the second method methanol is oxidized in air. Methanol vapors and a limited amount of air are passed

over a heated silver catalyst at 450 °C, as shown in Scheme 2. In this method, the condensate obtained is a mixture of formaldehyde, methanol and water. The excess methanol is removed by distillation and the resulting mixture is known as formalin (40% HCHO, 8% CH_3OH and 52% H_2O).

$$2CH_3OH + O_2 \xrightarrow[450\,^\circ C]{Ag} 2HCHO + 2H_2O$$

Scheme 2

Thirdly methane or propane–butane mixtures (from natural gas) can be oxidized in the presence of various metallic oxides, as shown in Scheme 3.

$$CH_4 + O_2 \xrightarrow{\text{metallic oxides}} HCHO + H_2O$$

Scheme 3

4 USES

Formaldehyde is a powerful disinfectant and antiseptic and is used for preserving anatomical specimens. Its main uses are in making plastics. Formaldehyde is condensed with urea and phenols to make plastics, with ammonia to give hexamethylenetetramine, a urinary antiseptic, and is also used to make RDX. Formaldehyde binds to the amino group of proteins, thus rendering toxic proteins harmless, but does not change their immunological properties. This is the basis for the production of the polio vaccine, and the tetanus and diphtheria toxoids.

5 EXTRACTION OF FORMALDEHYDE FROM DIFFERENT MATRICES

5.1 Air

Formaldehyde can be sampled from air using bubblers, impingers, mist chambers, sorbent cartridges, etc., in different media. The more commonly used media include water, MBTH, and chromotropic acid. Details of specific sampling methods are covered in the appropriate section.

5.2 Rainwater/Drinking Water/Wastewater

These samples can be analyzed directly by any colorimetric or chromatographic method.

5.3 Toothpaste

1 g of the paste is dissolved in 5 mL of 0.1 N NaOH diluted to 100 mL with distilled water. An aliquot is used to estimate the formaldehyde concentration.

5.4 Tablet

The tablet is weighed and 200 mL water is added. The solution is refluxed for 30 min, then the condenser is cooled and rinsed out. The solution is diluted to 500 mL and filtered. An aliquot of the filtrate is used to estimate the formaldehyde concentration.

5.5 Formal

The sample is dissolved in water and is diluted to a volume such that the equivalence of formaldehyde is approximately 0.05 mg mL^{-1}. This solution is used to estimate the formaldehyde concentration.

5.6 Crystalline Formal

The sample (20–40 mg) is dissolved in 1 : 2 H_2SO_4 and is diluted to 1 L. The solution is heated and incubated for 2 h and then cooled. An aliquot of the solution is used to estimate the formaldehyde concentration.

5.7 Cellulose

The sample (0.1 g) is added to 100 mL of 1 : 2 H_2SO_4. The solution is sealed and incubated at 90 °C for 2 h and then cooled. An aliquot of the solution is used for estimation.

5.8 Milk

Milk samples can be analyzed directly using any colorimetric method or any standard technique.

5.9 Urine

A few drops of 50% NaOH solution are added to the sample to precipitate the phosphate, and the mixture is then shaken well and filtered. An aliquot of the solution is used to estimate the formaldehyde concentration.

6 ANALYSIS

6.1 Qualitative Analysis (Snell[42])

6.1.1 Colorimetric Spot Test Method

Reagent	Color	Sensitivity	Interferences
1. Modified Schiff's reagent	Blue	<1 ppm	Acrolein, glyoxylic acid
2. Chromotropic acid	Violet	3 ppm	Glyceraldehyde, furfural
3. Potassium ferricyanide+ phenylhydrazine	Red	<15 µg	Higher aldehydes

hydrochloride +sodium hydroxide			
4. Acetyl acetone +ammonium acetate + acetic acid	Yellow	–	Large amount of acetaldehyde
5. Phenylhydrazine	Red	1 μg	Not specified
6. Ammoniacal silver nitrate (Tollens' reagent)	Black ppt	2 ppm	Not specified
7. 2,7-Dihydronaphthalene	Violet	0.5–2.0 μg mL^{-1}	Acrolein
8. Morphine hydrochloride +sulfuric acid	Violet ring at liquid junction	<5%	Not specified
9. 2-Hydroxycarbazole sulfuric acid	Dark blue	0.004 μg	Pyruvaldehyde
10. 2-Methyl-3-benzohydrazine hydrochloride +ferric chloride	Deep blue	0.1 μg	Not specified

6.1.2 Derivatives

6.1.2.1 Methylene Bismethone A few drops of a 5–10% solution of methone or dimedon (dimethyl dihydro resorcinol), and 5,5-dimethylcyclohexanediene in ethanol are added to the sample which has been made slightly acidic with acetic acid. A precipitate of methylene bismethone is formed, and, recrystallized from methanol and water (mp 189 °C).

6.1.2.2 Formaldehyde p-*nitrophenyl Hydrazone*
A few drops of *p*-nitrophenyl hydrazine hydrochloride in mildly acidic ethanol are added to a solution containing formaldehyde. A precipitate of formaldehyde *p*-nitrophenyl hydrazone is formed, and recrystallized from ethanol (mp 181–182 °C).

6.1.2.3 Formaldehyde 2,4-dinitrophenyl hydrazone
A few drops of 2,4-DNPH hydrochloride in mildly acidified ethanol are added to a solution containing formaldehyde. A precipitate of formaldehyde 2,4-dinitrophenyl hydrazone is formed, and, recrystallized from ethanol (mp 166–167 °C).

6.1.2.4 Methylene Dinaphthol A few drops of a formaldehyde-containing solution are treated with 33% alcohol, β-naphthol and a little hydrochloride. A precipitate of methylene dinaphthol is formed. On gently boiling small white needles are formed, which turn brown at 180 °C, and melt with decomposition to a brownish-red liquid at 189–192 °C.

6.2 Quantitative Analysis

6.2.1 Titrimetric Methods

Titrimetric methods, because of their simplicity and accuracy, are widely employed for the determination of formaldehyde concentration when present as a major component. However, there is a limit for aldehyde concentration below which it is inadvisable to expect great accuracy. An assessment of these methods has been carried out by Buchi,[43] and by Reynolds and Irwin.[35] Reynolds and Irwin[35] reviewed the different titrimetric methods available and concluded that for measuring small quantities of pure formaldehyde, the iodimetric method is most suitable. The potassium cyanide method is the best volumetric method for the estimation of formaldehyde concentration in the presence of acetone, acetaldehyde, benzaldehyde, higher aldehydes and ketones. The sodium sulfite method is very simple and adaptable to field tests. The hydroxylamine hydrochloride method has the disadvantage of being insufficiently sensitive for low concentrations and is rather slow, requiring several hours for completion. For colored solutions the pH titration method has a distinct advantage, but it is no better than ordinary titration in the case of colorless solutions.

6.2.1.1 Sodium Sulfite Method

Principle. When formaldehyde reacts with sodium sulfite, it forms the formaldehyde bisulfite addition product, and sodium hydroxide is liberated quantitatively according to Scheme 4.

$$CH_2O + Na_2SO_3 + H_2O \longrightarrow NaOH + CH_2(NaSO_3)OH$$

Scheme 4

The amount of base produced is determined titrimetrically.

Reagents. The following reagents are used: (a) Na_2SO_3 (125 g of anhydrous sodium sulfite or 250 g of hydrated sodium sulfite is dissolved in water and diluted to 1 L); (b) 0.25 N H_2SO_4.

Procedure. To 100 mL sodium sulfite solution in a Erlenmeyer flask, *W* g (about 2 g) of the sample is added and the mixture is swirled to effect complete reaction. Then 3–5 drops of 1% ethanolic thymolphthalein indicator solution are added and the solution is titrated with 0.25 N H_2SO_4 to the colorless end-point. A blank determination is also carried out.

Calculation.

$$\text{HCHO (wt\%)} = \frac{(A - B)(N)(MW)(100)}{(W)(1000)}$$

where A = volume of sulfuric acid solution required for sample titration (mL), B = volume of sulfuric acid solution required for blank titration (mL), N = normality of the sulfuric acid solution, MW = molecular weight of formaldehyde (30.03 g) and W = sample weight (g).

6.2.1.2 Alkaline Peroxide Method

Principle. Formaldehyde is oxidized with H_2O_2 in the presence of excess base according to Scheme 5.

$$2HCHO + 2\,NaOH + H_2O_2 \longrightarrow 2\,HCOONa + 2H_2O + H_2$$

Scheme 5

Excess NaOH is determined by titration with standard acid.

Interferences. Acetone (less than 7 wt%) and acetaldehyde (less than 0.5 wt%) do not interfere.[43]

Reagents. The following reagents are used: (a) 1 N NaOH; (b) neutral H_2O_2 (10 mL of 30% H_2O_2 is neutralized with 1 N NaOH using bromothymol blue as an indicator and diluted to 100 mL); (c) 1 N H_2SO_4.

Procedure. Water (10 mL) is placed in a stoppered 250 mL Erlenmeyer flask and weighed, then 3 mL of sample is added and the flask is weighed again. To this 50 mL of 1 N NaOH solution is added and then immediately but slowly 50 mL of neutral H_2O_2 solution is added. The mixture is heated on a water bath for 15 min, while shaking cautiously with a general rotatory motion. It is cooled to room temperature with cold water. The excess NaOH is titrated with 1 N H_2SO_4 using 2–3 drops of bromothymol blue as indicator to a bluish-green endpoint. A blank determination is also made.

Calculation.

$$\text{HCHO (wt\%)} = \frac{(B - A)(N)(MW)(100)}{(W)(1000)}$$

where A = volume of sulfuric acid solution required for sample titration (mL), B = volume of sulfuric acid solution required for blank titration (mL), N = normality of the sulfuric acid solution, MW = molecular weight of formaldehyde (30.03 g), and W = sample weight (g).

6.2.1.3 Iodimetric Method

Principle. The reaction of formaldehyde with hypoiodite reagent serves as a method for determination, according to Scheme 6.

$$HCHO + NaOI + NaOH \longrightarrow HCOONa + NaI + H_2O$$

Scheme 6

In acidic media iodide self-oxidizes into iodine, as shown in Scheme 7.

$$4I^- + O_2 + 4H^+ \longrightarrow 2I_2 + H_2O$$

Scheme 7

Many other aldehydes and ketones also react with the iodine reagent and the method described is basically useful only with known systems. The recovery of formaldehyde is approximately 98.5%.

Interferences. The interference of methanol, a known constituent in commercial formaldehyde solutions, has been disputed. This iodimetric method is particularly useful for the determination of small concentrations of formaldehyde in aqueous solution.

Reagents. The following reagents are used: (a) 3 N NaOH; (b) 0.2 N NaOI; (c) 0.1 N $Na_2S_2O_3$; (d) H_2SO_4.

Procedure. A sample containing up to 0.16 g of formaldehyde is weighed into an iodine flask and diluted with water to about 100 mL. Then 30 mL of 3 N sodium hydroxide solution and 75 mL of 0.2 N sodium hypoiodite are added and the flask is stoppered. The mixture is allowed to stand at room temperature for 30 min. Approximately 95 mL of H_2SO_4 is added and the liberated iodine is titrated immediately with 0.1 N sodium thiosulfate solution using starch indicator. At least one blank determination is carried out with each set of samples.

Calculation.

$$\text{HCHO (wt\%)} = \frac{(B - A)(N)(MW)(100)}{(W)(1000)}$$

where A = volume of sodium thiosulfate solution required for sample titration (mL), B = volume of sodium thiosulfate solution required for blank titration (mL), N = normality of the sodium thiosulfate solution, MW = molecular weight of formaldehyde (30.03 g), and W = sample weight (g).

6.2.1.4 Potassium Cyanide Method

Principle. Formaldehyde reacts with potassium cyanide, unreacted cyanide is converted into silver cyanide by the addition of a measured amount of standard silver nitrate solution and excess silver nitrate is determined by titration with thiocyanate as shown in Schemes 8 and 9.

$$HCHO + KCN \longrightarrow CH_2(OK)CN$$

Scheme 8

$$KCN + AgNO_3 \longrightarrow AgCN + KNO_3$$

Scheme 9

Reagents. The following reagents are used: (a) 0.1 N KCN; (b) 0.1 N $AgNO_3$; (c) 0.1 N KCNS.

Procedure. A sample containing approximately 0.15–0.25 g of dissolved formaldehyde is weighed and added to a 200 mL glass-stoppered Erlenmeyer flask containing 100 mL of 0.1 N KCN. After shaking, the mixture is washed into a volumetric flask with 40 mL of 0.1 N $AgNO_3$ and 10 mL of 1 : 9 nitric acid. The volume is made up to 200 mL. The solution is filtered and 100 mL of the filtrate is titrated with 0.1 N KCNS solution using ferric alum as an indicator.

Calculation.

$$\text{HCHO (wt\%)} = \frac{[100 - (40 - 2A)](N)(MW)(100)}{(W)(1000)}$$

where A = volume of thiocyanate solution required for titration (mL), N = normality of the thiocyanate solution, MW = molecular weight of formaldehyde (30.03 g) and W = sample weight (g).

6.2.1.5 Ammonium Chloride Method

Principle. The reaction is shown in Scheme 10.

$$6HCHO + 4NH_3 \longrightarrow (CH_2)_6N_4 + 6H_2O$$

Scheme 10

This reaction is the basis for a quantitative determination, with the excess ammonia being determined by steam distillation or by titration. Buchi[43] modified the technique for the use of neutral NH_4Cl.

Interferences. Ethanol and acetone have no significant effect on the analysis, but acetaldehyde in concentrations higher than 5% leads to high values.

Reagents. The following reagents are used: (a) 1 N NaOH; (b) neutral NH_4Cl; (c) 1 N HCl.

Procedure. A 6 g sample of approximately 37% formaldehyde solution is weighed into a 100 mL flask and diluted to the volume of the flask. Then 25 mL of this solution is added to an Erlenmeyer flask together with 3 drops of 0.1% bromothymol blue indicator and neutralized with NaOH solution until the indicator color changes to blue. Neutral NH_4Cl (1.5 g) and NaOH solution (25 mL) are added rapidly, the flask is closed tightly using silicon grease to ensure a perfect seal and the reaction mixture is allowed to stand for 1.5 h. The excess NH_3 is titrated with HCl until the color changes to green. A blank determination is also carried out.

Calculation.

$$\text{HCHO (wt\%)} = \frac{(B - A)(N)(180.2)(100)}{W(1000)}$$

where A = volume of hydrochloric acid required for sample titration (mL), B = volume of hydrochloric acid required for blank titration (mL), N = normality of hydrochloric acid and W = sample weight (g).

6.2.1.6 Mercurimetric Method

Principle. The reaction is shown in Scheme 11.

$$K_2HgI_4 + HCHO + 3NaOH \longrightarrow Hg + HCOONa + 2KI + 2NaI + 2H_2O$$

Scheme 11

The precipitated Hg is determined iodimetrically.

Interferences. Organic hydroperoxide and acetaldehyde in concentrations as low as 0.5% can cause interference. Acetone and methyl and ethyl alcohols have no appreciable effect.

Reagents. The following reagents are used: (a) mercuric chloride; (b) KI solution; (c) 2 N NaOH; (d) 2 N acetic acid; (e) 0.1 N iodine solution; (f) 0.1 N sodium thiosulfate.

Procedure. A 1.75 g sample of 37% formaldehyde solution or its equivalent is weighed into a 500-mL volumetric flask and diluted to the volume of the flask. A 25-mL portion of this solution is added to a 200-mL glass-stoppered Erlenmeyer flask, containing a solution of 1 g of mercuric chloride and 2.5 mL of KI in 35 mL of water. Then 20 mL of 2 N NaOH is added. The mixture is shaken vigorously for 5 min then acidified with 25 mL of 2 N acetic acid. Immediately 25 mL of 0.1 N iodine solution is added and the mixture is agitated until the precipitate is completely dissolved. The excess iodine is back-titrated with 0.1 N sodium thiosulfate solution using starch solution as the indicator. A blank determination is also carried out.

Calculation.

$$\text{HCHO (wt\%)} = \frac{(B - A)(N)(MW)(100)}{W(2)(1000)}$$

where B = volume of sodium thiosulfate solution required for blank titration (mL), A = volume of sodium thiosulfate solution required for sample titration (mL), N = normality of the sodium thiosulfate solution,

MW = molecular weight of formaldehyde (30.03 g) and W = sample weight (g) in 25 mL.

6.2.1.7 Hydroxylamine Method The hydroxylamine method is widely used for the determination of carbonyl compounds in the presence of alkaline-sensitive products and impurities, such as phenol, cresol and resinous materials. Formaldehyde reacts with hydroxylamine hydrochloride forming an oxime and liberating hydrochloric acid as shown in Scheme 12. Using a suitable acid–base indicator (or preferably by pH titration when the solutions are colored) the reaction can serve as a basis for quantitative estimation.

$$HCHO + H_2NOH{\cdot}HCl \longrightarrow HCN{=}NOH + HCl + H_2O$$

Scheme 12

Reagents. The following reagents are used: (a) hydroxylamine hydrochloride; (b) 0.1 N sodium hydroxide.

Procedure. To 10 mL 1 N hydroxylamine hydrochloride solution in an Erlenmeyer flask, W g (about 2 g) of sample is added and agitated. After agitation, the mixed solutions are neutralized with 0.1 N sodium hydroxide solution using methyl orange as indicator. It is essential to match the end-point (which is red to orange and not yellow) against a blank. The method is reported as being sensitive to 0.1 mg of formaldehyde. A blank determination is also carried out.

Calculation.

$$\text{HCHO (wt\%)} = \frac{(A - B)(N)(MW)(100)}{W(1000)}$$

where A = volume of sodium hydroxide solution required for sample titration (mL), B = volume of sodium hydroxide solution required for blank titration (mL), N = normality of sodium hydroxide solution, MW = molecular weight of formaldehyde (30.03 g) and W = sample weight (g).

6.2.2 Colorimetric Methods

Absorption spectrophotometry forms the basis for many of the aldehyde monitoring techniques. The chromotropic acid method is used widely and is approved protocol for the measurement of formaldehyde.[44,45] The method is specific for formaldehyde but is not very sensitive. Another commonly used colorimetric method utilizes pararosaniline as the chromogen since it gives an enhancement in the sensitivity by approximately a factor of 2 over the chromotropic acid method. However, the technique is prone to interference from carbonyl compounds and other low-molecular-weight aldehydes. The modified pararosaniline method[18] is not affected by phenol : formaldehyde ratios ranging from 1 to 100, whereas such ratios cause total inhibition of the chromotropic acid method. Miksch et al.[18] concluded that the modified pararosaniline method was more sensitive, more reproducible and easier to use than the chromotropic acid method. Another important method uses MBTH for formaldehyde measurement. This method's sensitivity has been reported as 30 ppb formaldehyde based on a sampled air volume of 25 L in 35 mL of absorbing solution. Several other colorimetric methods for formaldehyde have also been reported. These include the 7-amino-5-hydroxy-2-naphthalene sulfamic acid and the *p*-phenylenediamine methods.

To perform large numbers of analyses or for semicontinuous analysis of water or air, colorimetric analyses can be adapted for use with autoanalyzers. Autoanalyzers are usually implemented by one of two methods: either continuous or discrete (batch). In a continuous flow analysis, samples are analyzed from a flowing stream with any necessary operations (such as filtering and reagent addition) performed prior to the measurement of chemical and physical properties. Actual determinations are made using flow-through sample cells. In discrete analysis, samples are placed in individual containers for the duration of the analysis. Preliminary operations of dilution, reagent addition and mixing are performed on each sample at different locations within the analyzer. Each treated sample is then presented in sequence to the sensing device. A batch of samples is usually preloaded for processing by this technique. While both technique are used in process control and laboratory analyses, continuous analysis is more often utilized in automated process control applications because of its faster response time.[46]

All the colorimetric methods covered here relate to formaldehyde analysis in air and require specific sampling methods, although these methods could also be used directly for estimation of formaldehyde in solutions.

6.2.2.1 Chromotropic Acid Method

Principle. Formaldehyde reacts with chromotropic acid (1,8-dihydroxynaphthalene 3,6-disulfonic acid) in concentrated sulfuric acid solution to form a purple colored dye, which is determined spectrophotometrically at 580 nm. The formaldehyde may be collected either in water, in aqueous bisulfite or directly in the chromotropic acid–sulfuric acid solution. By collecting in water 0.1–2.0 $\mu g\,mL^{-1}$ formaldehyde can be measured. This corresponds to a minimum detectable quantity of 0.1 ppm in a 40-L air sample collected in 20 mL water. The sensitivity can be increased 10-fold by sampling directly into the chromotropic acid–sulfuric acid solution. The reproducibility of the method is within ±5%.[47]

Interferences. The chromotropic acid method has very little interference from other aldehydes (<0.01% from saturated aldehydes and a few percent from acrolein). Alcohols, phenols, aromatic hydrocarbons and olefins all show negative interference but the concentrations of these classes of compounds in ambient air are too low to lead to serious errors.

Apparatus. Two coarse-fritted bubblers in series are used to collect the samples. A pump capable of maintaining a metered flow of 1 L min^{-1} through the sampling train for up to 24 h is required.

Reagents. The following reagents are used: (a) chromotropic acid reagent (0.10 g of chromotropic acid disodium salt is dissolved in water and diluted to 10 mL, filtered if necessary and stored in the dark. Fresh solution is made weekly); (b) concentrated H_2SO_4 (specific gravity = 1.86); (c) stock formaldehyde solution (1 mg mL^{-1}) (2.7 mL of 37% formalin solution is diluted to 1 L with distilled water. This solution is standardized by the addition of excess sodium bisulfite to an aliquot of the solution, followed by iodimetric titration of the formaldehyde bisulfite addition product after the excess bisulfite has been oxidized by I_2. Alternatively, sodium formaldehyde bisulfite can be used as a primary standard, in which case 4.470 g of formaldehyde bisulfite is dissolved in distilled water and diluted to 1 L. This solution is stable for at least three months); (d) dilute standard formaldehyde solution (10 μg mL^{-1}) (1 mL of standard stock solution is diluted to 100 mL with distilled water. Fresh solution is prepared daily).

Procedure. Distilled water (20 mL) is placed in each bubbler, and the sampling train is connected and aspirated at 1 L min^{-1} for a suitable time to collect enough formaldehyde for analysis (24 h). The collection efficiency in a single bubbler is approximately 80%, i.e. 95% of the formaldehyde is trapped using two bubblers. After sampling, the volume is adjusted to 20 mL and a 4-mL aliquot of the sample is pipetted to the stoppered test tube. A blank is also prepared using 4 mL distilled water. A 0.1 mL portion of 1% chromotropic acid solution is added and mixed, then 6 mL concentrated sulfuric acid is cautiously added from a pipette. The solution is allowed to cool and the absorbance is read at 580 nm in a 1-cm cell. The amount of formaldehyde present in each aliquot taken is determined from the calibration curve obtained as described next.

Calibration. A freshly prepared standard formaldehyde solution (10 μg formaldehyde mL^{-1}) is used to prepare the calibration solution. Different amounts (0, 0.1, 0.3, 0.5, 0.7, 1.0 and 2.0 mL) of this solution are pipetted into a series of glass-stoppered graduated tubes. Each sample is diluted to 4 mL with distilled water and the color is developed as described above. The absorbance is plotted against formaldehyde concentration (μg mL^{-1}). The air concentration of formaldehyde is calculated as follows:

$$\text{ppm (volume)} = \frac{\text{total HCHO}(\mu g) \times 24.47}{VM}$$

where total formaldehyde is the sum of the amounts collected in each bubbler, V is the volume of air sampled (at 101.325 kPa and 25 °C) and M is the molecular weight of formaldehyde (30.03 g).

6.2.2.2 3-Methyl-2-benzothiazole Hydrazone Method

Principle. The formaldehyde in ambient air is collected in a 0.05% aqueous solution of 3-methyl 2-benzothiozolone hydrazone hydrochloride. The resulting azine is then oxidized by ferric chloride/sulfamic acid solution to form a blue cationic dye in acid solution which can be measured at 628 nm after 12 min (Figure 2). The concentration of total aldehydes is calculated in terms of formaldehyde, and formaldehyde in the range 0.03–0.7 μg mL^{-1} can be measured. This corresponds to a minimum detectable concentration of 0.03 ppm in a 25-L air sample. The reproducibility of the method is within ±5%.[47]

Apparatus. The samples are collected in all-glass bubblers with a coarse fritted inlet. It is normally necessary to sample ambient air for quite long periods to obtain sufficient aldehyde for analysis and a pump capable of drawing at least 0.5 L min^{-1} for 24 h is required. A critical orifice, a rotameter or a gas meter can be used to meter the flow.

Figure 2 Sequence of reactions involved in the MBTH method. A = 3-methyl-2-benzothiazolone hydrazone, B = azine, C = reactive cation, D = blue cationic dye. (Reprinted with permission from Sawicki et al.[26] Copyright 1961 American Chemical Society.)

Reagents. The following reagents are used: (a) MBTH (0.05%) (0.5 g of MBTH is dissolved in distilled water and diluted to 1 L. The reagent becomes turbid either on storage or during sampling. If this occurs, it is filtered by gravity. The solution is stable for a week or more if stored in the cold in a dark bottle); (b) oxidizing reagent (1.6 g sulfamic acid and 1.0 g ferric chloride is dissolved in distilled water and diluted to 1 L); (c) stock formaldehyde solutions (1.0 mg mL^{-1}, prepared as in chromotropic acid method); (d) dilute standard formaldehyde solution (10 μg mL^{-1}, prepared as in chromotropic acid method).

Procedure. A measured volume of ambient air at a rate of 0.5 L min^{-1} is sampled through 35 mL of MBTH solution in the absorber until sufficient aldehyde for analysis has been collected. An average collection efficiency of 84% has been determined for sampling under these conditions although higher efficiencies have been reported for slightly modified conditions. The efficiency is between 90 and 95% using 10 mL of 0.2% aqueous MBTH in a bubbler aspirated at 1 L min^{-1}.

After sampling the volume of absorbing reagent solution is made up to exactly 35 mL with distilled water (to compensate for evaporation losses) and allowed to stand for 1 h. Then 10 mL of the sample solution is pipetted into a glass-stoppered tube and an equal volume of reagent is pipetted into a second tube to serve as a blank. A 2 mL portion of oxidizing solution is added to each tube and mixed well. After allowing to stand for at least 12 min the absorbance of the sample is read at 628 nm against the reagent blank in 1-cm cells. The aldehyde content (expressed as μg formaldehyde mL^{-1}) is determined from the calibration plot prepared as described.

Calibration. Freshly prepared dilute standard formaldehyde solution is used to calibrate this method. Different amounts (0, 0.5, 1.0, 3.0, 5.0 and 7.0 mL) of this solution are pipetted into a series of 100 mL volumetric flasks and diluted to the volume of the flask with 0.05% MBTH solution. After allowing to stand for 1 h, 10 mL aliquots of each of these solutions are transferred to stoppered test tubes. Oxidizing solution (2 mL) is added and mixed well. After 12 min the absorbance of each solution is determined at 628 nm against the blank in 1-cm cells. Absorbance is plotted against μg formaldehyde per mL of solution. The air concentration of total aliphatic aldehydes (as formaldehyde) is given by:

$$\text{ppm (volume)} = \frac{\mu\text{g mL}^{-1}\text{HCHO} \times 35 \times 24.45}{VME}$$

where V = volume of air sampled (at 101.325 kPa and 25 °C), M is molecular weight of formaldehyde (30.03 g) and E is the collection efficiency of the bubbler which can be estimated by using two bubblers in series. If a coarse-fritted bubbler is used, E may be taken to be 0.84%.

6.2.2.3 Nash Method

Principle. Formaldehyde reacts with ammonium acetate, acetic acid and acetylacetone (Nash reagent) and forms the blue compound diacetyldihydrolutidine.[48] The detection limit and precision of the method are 0.05 μg mL^{-1} and 1.43%.[49]

Apparatus. A mist chamber, filter holder, pump and rotameter/gas meter are required.

Reagents. The following reagents are used: (a) Nash reagent (75 g of ammonium acetate, 1.5 mL acetic acid, and 1.0 mL acetylacetone are placed in a volumetric flask and made up to 500 mL with distilled water); (b) stock formaldehyde solution (as described for chromotropic acid method); (c) standard formaldehyde solution (as described for chromotropic acid method).

Procedure. Formaldehyde is sampled using the mist chamber technique. The air is first passed through a 1.2-μm pore size poly(tetrafluoroethylene) (PTFE) filter to remove particles and then exposed to a fine spray of deionized water (25 mL) with a flow rate of 12 L min^{-1}.[49,50] After sampling, the volume of absorbing reagent solution is made up to exactly 25 mL with distilled water (to compensate for evaporation losses). Then 5 mL of Nash reagent and 5 mL of sample solution are placed in a test tube. After allowing to stand for at least 10 min, the absorbance of the sample is determined at 412 nm against the reagent blank (water) in a 1-cm cell. Formaldehyde can be determined from the calibration plot prepared as described next.

Calibration. A freshly prepared, dilute standard formaldehyde solution containing 10 μg formaldehyde mL^{-1} is used to prepare calibration solutions. Different amounts (0, 2, 4, 6 and 8 mL) of this solution are added into a series of 10-mL volumetric flasks and diluted to the volume of the flask with water. A 5-mL aliquot of each solution is transferred to a stoppered test tube and 5 mL of Nash reagent is added and mixed well. After 10 min the absorbance of each solution is determined at 412 nm against the blank in 1-cm cells. The absorbance is plotted against μg formaldehyde mL^{-1} of solution.

6.2.2.4 Modified Pararosaniline Method

Principle. Acid-bleached pararosaniline and formaldehyde lead to the formation of intensely colored pararosaniline methyl sulfonic acid which is read at

Figure 3 Reaction pathway for pararosaniline method. (Reprinted with permission from Miksch et al.[18] Copyright 1981 American Chemical Society.)

570 nm (Figure 3). The reproducibility of the slope is $0.52 \pm 0.37\ mL^{-1}$.

Only low-molecular-weight aldehydes give positive interferences, and only when present in a large excess compared with formaldehyde. Negative interferences could be caused by compounds that react with either pararosaniline or formaldehyde. Cyanide, sulfite and hydroxylamine all form stable, well-characterized adducts with formaldehyde.[18]

Reagents. The reagents used are formaldehyde stock solution, pararosaniline solution and sodium sulfite. Details are given below. Methanol-free formaldehyde solutions are prepared by refluxing approximately 20 g of paraformaldehyde in water, filtering the solution and diluting to 1 L. The solution is standardized by adding the formaldehyde solution to a 1 M solution of sodium sulfite to quantitatively produce sodium formaldehyde bisulfite and hydroxyl ions. It is back-titrated to its original pH using 1.0 M HCl to determine the amount of formaldehyde added. The stock solution is stable for several months.

Pararosaniline (0.16 g) is dissolved in 20 mL of concentrated HCl and the mixture is diluted to 100 mL with deionized water. This reagent remains stable for several months when stored in an amber bottle.

Sodium sulfite (8 mM) is prepared by dissolving 0.10 g of anhydrous sodium sulfite in deionized water and

diluting the solution to 100 mL with deionized water. It is prepared daily.

Procedure. A 2.5-mL sample of formaldehyde solution is placed in a cuvette and 250 µL of acidified pararosaniline reagent is added. After mixing thoroughly, 250 µL of the sodium sulfite reagent is added. The cuvette is capped and placed in a water bath at 25 °C. The color is allowed to develop for 60 min and read at 570 nm. The blank and the sample are read against deionized water.

Calibration. Freshly prepared standard formaldehyde solution (0.06 mg mL^{-1}), is used to calibrate this method. Different amounts (0, 0.5, 1.0, 3.0, 5.0 and 7.0 mL) of this solution are pipetted into cuvettes and 250 µL of acidified pararosaniline reagent is added. After mixing thoroughly, 250 µL of the sodium sulfite reagent is added. The cuvettes are capped and placed in a water bath at 25 °C. The color is allowed to develop for 60 min and read at 570 nm. The blank and the sample are read against deionized water.

6.2.3 Polarographic Method

The polarographic technique has gained favor as a practical method for the determination of formaldehyde and other aldehydes.[51] The increase in popularity of the polarographic technique may be attributed to improved electrode design and automated microprocessor-based differential pulse polarography. A pulse technique that is capable of good signal-to-noise ratios employs the pulse train shown in Figure 4. The formaldehyde–hydrazone derivative could be determined in acetate buffer solution by differential pulse polarography. An aliquot of the derivatized solution is then analyzed by differential pulse polarography with a dropping mercury electrode.[52]

6.2.3.1 Principle Polarography involves the study of current–voltage relationships at a dropping mercury electrode under certain controlled conditions. It consists

Figure 4 Pulse train, voltage and current pulses for differential pulse polarography.[52]

Figure 5 (a) Schematic diagram of polarographic cell; (b) circuit for obtaining polarograms. (Reproduced by permission from Willard et al.[46])

in electrolyzing a solution of an electroactive substance between a dropping mercury electrode functioning as a cathode, and some reference electrode (a pool of mercury) which acts as an anode. The area of the anode is correspondingly large so that it may be regarded as incapable of becoming polarized and the potential of such an electrode remains fairly constant. A potential is applied between these electrodes and increased in a

stepwise manner. At first only a small current flows (the so-called residual current), and this continues until the decomposition of the reducible ionic species is reached. Figure 5 shows the polarographic cell and a basic circuit for obtaining a polarogram.

A steep rise in the current is observed, which continues to rise with increasing potential until it reaches a maximum value when the concentration of ions at the electrode surface approaches zero. Now the current no longer increases with applied potential but approaches a steady limiting value. The particle reduced at the mercury surface diffuses away from the surface either by forming an amalgam with the mercury, which subsequently detaches from the capillary top or by simply diffusing back into the bulk of the solution.

Septon and Ku[36] have described a method for polarographic determination of formaldehyde in air samples. This polarographic method is free from interferences from acetaldehyde, acrolein and benzaldehyde as their potential differences are different from that of formaldehyde. Therefore, this technique can be used to monitor formaldehyde where incomplete combustion occurs since it is possible to resolve formaldehyde from other aldehydes. Septon and Ku[36] determined the collection efficiency by connecting two sampling devices in series. The efficiency was determined from the amount of vapor that passed through the first bubbler and was absorbed in the backup. The efficiency was $98.6 \pm 0.3\%$ for six samples when 10 ppm formaldehyde was collected at a flow rate of $1\,L\,min^{-1}$ for 30 min in a bubbler containing 10% methanol–water solution.

This method was validated by generating samples with concentration of $5.8–17.7\,mg\,m^{-3}$. Average recovery was 103%. The pooled coefficient of variation or relative standard was 0.08. A linear regression of formaldehyde taken vs formaldehyde found showed correlation with a slope of 1.1 and an intercept of $-1.4\,mg\,m^{-3}$. The quantitative determination limit is 50 ppb, and the relative standard deviation of replicate determinations at this level was 0.04.

6.2.3.2 Sampling Air (30 L) is sampled in 10% v/v methanol/deionized water in a bubbler connected to a sampling pump at a flow rate of $0.5–1\,L\,min^{-1}$. A prefilter of mixed cellulose acetate membrane (0.8-μm pore size and 37 mm diameter) with a 37 mm polystyrene filter holder is used. The maximum volume sampled should not exceed 160 L at $1\,L\,min^{-1}$. The bubbler is connected to the sampling pump with rubber tubing (poly(vinyl chloride) (PVC) tubing should not be used before the bubbler). If evaporation losses occur during the sampling, additional solution is added to the bubbler to maintain the required concentration of methanol solution. With each batch of ten samples at least one blank is subjected to the same handling except that no air is drawn through it. The bubbler solution is transferred to a 20-mL glass vial.

6.2.3.3 Reagents Details of reagents to be used are as follows. Methanol solution (10% v/v) is prepared by diluting 100 mL of reagent grade methanol to 1 L with deionized water. The acetate buffer (pH 4) is an equimolar mixture of acetic acid and sodium acetate (0.1 M) in deionized water. For the hydrazine reagent (2% w/v) 2 g of hydrazine sulfate ($H_2NNH_2 \cdot H_2SO_4$) is dissolved in deionized water and diluted to 100 mL with deionized water. It is prepared fresh every week and kept tightly closed. The supporting electrolyte is prepared by mixing 10% methanol solution, acetate buffer and 2% hydrazine reagent in a ratio of 5 : 4 : 1, respectively. A 100-mL portion of this solution is required for each analysis and is prepared fresh daily. The formaldehyde stock solution (1000 ppm) is prepared by dissolving 2.7 g (about 3 mL) of 37% formaldehyde solution in 1 L of deionized water. The solution is stable for 3 months. Appropriate serial dilutions of the formaldehyde stock solution are made with 10% methanol to prepare 100 ppm, 10 ppm and 1 ppm formaldehyde solutions.

Reagents used for standardization of formaldehyde stock solutions are: sodium carbonate (certified 99.9% minimum purity, dried at 120 °C for 2 h, then transferred to a desiccator, dried to a constant weight and used as a primary standard); concentrated (98%) sulfuric acid; 0.1 N sulfuric acid (standardized against sodium carbonate solution); and 12.5% (w/v) sodium sulfite.

Standardization of formaldehyde stock solutions involves weighing 50 ± 0.5 g of formaldehyde solution and transferring it to a 250-mL beaker, then adding 25 mL of 12.5% w/v sodium sulfite (whose pH is adjusted to 9.6 with 0.1 N H_2SO_4) and titrating to pH 9.6 with 0.1 N H_2SO_4. The concentration of formaldehyde (in ppm) is calculated as follows:

$$\text{Formaldehyde (ppm)} = \frac{(A - B)(C)(D)}{E}$$

where A = sulfuric acid solution required to titrate the sample (mL), B = sulfuric acid solution required to titrate the blank (mL), C = normality of the sulfuric acid solution (mequiv mL^{-1}), D = (30 mg mequiv^{-1} of HCHO) × (1000 μg mg^{-1}) or 30×10^3 μg mequiv^{-1} of formaldehyde, and E = amount of sample used (g).

6.2.3.4 Sample Preparation The total volume of each sample is measured and recorded and the volume is made up with 10% methanol. Then 5 mL of the sample solution, 4 mL of acetate buffer and 1 mL of 2% hydrazine reagent are added to the polarographic cell.

6.2.3.5 Analysis All glassware and polarographic cells are soaked in 6 M nitric acid, rinsed thoroughly

with deionized water and air-dried prior to use. The polarographic analyzer and the automated cell sequencer are warmed up for at least 30 min. Each standard and sample are purged for 5 min with pre-purified nitrogen. A calibration curve is made by analyzing standards and blanks (supporting electrolyte). The standard is reanalyzed after every five or six samples. The peak current (nA) for each standard and sample is recorded. The differential pulse polarogram of formaldehyde hydrazone at a dropping mercury electrode yields a peak at approximately −0.850 V. A least squares regression program is used to plot a calibration curve of peak current (nA) vs concentration (total μg) of standards.

6.2.3.6 Calculations The weight in μg corresponding to each response (nA) is recorded from the standard curve. No volume corrections are needed if the standard curve is based upon μg per 10 mL formaldehyde and the volume of the sample determined is identical to the volume of the standards determined.

Corrections for the blanks must be made for each sample as follows:

$$\mu g\ mL^{-1} HCHO\ (\text{blank corrected}) = \frac{\mu g\ HCHO}{\text{sample aliquot (mL)}} - \frac{\mu g\ \text{blank}}{\text{blank aliquot (mL)}}$$

The concentration of formaldehyde in the air sampled can be expressed in $mg\,m^{-3}$, which is numerically equivalent to $\mu g\,L^{-1}$.

$$mg\ m^{-3} = \frac{(\text{corrected } \mu g\ mL^{-1})(\text{sample volume})}{(\text{air volume sampled, liters})}$$

Another method of expressing concentration is in ppm (corrected to standard conditions of 25 °C and 101.325 kPa):

$$\text{ppm} = mg\ m^{-3} \times \frac{24.45}{MW}$$

where 24.45 = molar volume (L mol^{-1}) of analyte, at 25 °C and 101.325 kPa, and MW = molecular weight (g mol^{-1}) of analyte.

6.2.4 Chromatographic Methods

6.2.4.1 Direct Gas Chromatographic Method

Principle. A direct gas chromatographic procedure is suitable for the quantitative determination of formaldehyde. In GC a mobile phase (a carrier gas) and a stationary phase (column packing) are used to separate individual compounds. The carrier gas is nitrogen or helium. The stationary phase is a liquid that has been coated on an inert granular solid, called the column packing, that is held in borosilicate glass tubing. The column is installed in an oven with the inlet attached to a heated injector block and the outlet attached to a detector. Precise and constant temperature control of the injector block, oven and detector is maintained. Stationary phase material and concentration, column length and diameter, oven temperature, carrier gas flow and detector type are the controlled variables. The sample solution is injected through a tetrafluoroethylene-coated silicone rubber septum onto the column with a microsyringe. The samples are vaporized and moved through the column at different rates, depending on differences in partition coefficients between the mobile and stationary phases. As each component passes through the detector a quantitatively proportional change in electrical signal is measured on a strip-chart recorder. The retention time is indicative of the particular component and the peak height/peak area is proportional to its concentration. The detector system may be selected on the basis of specificity and sensitivity needed.[53]

Apparatus. Numerous instruments varying in sophistication and price are available for GC. The basic components are shown in Figure 6. The different parts of the instrument are as follows:

- Carrier gas supply. Carrier gases, which must be chemically inert, include He, Ar, N_2 and H_2. He is the most widely used. Flow rates are controlled by a pressure regulator. Inlet pressure usually ranges from 69 to 345 kPa which leads to flow rates of 25–50 mL min^{-1}.
- Sample injection system. Column efficiency requires that the sample be of a suitable size and be introduced as a ''plug'' of vapor. A microsyringe is used to inject liquid samples through a rubber or silicone diaphragm into a heated sample port located at the head of the column. For ordinary analytical columns sample sizes vary from 0.1 to 10 μL. Capillary columns require much smaller samples ($\sim 10^{-3}$ μL).
- Columns. Two types of columns are employed. One type is fabricated from capillary tubing (0.3–0.5 mm i.d.), the bore of which is coated with a very thin film (1 μm) of the liquid phase, and is 10–100 m long. Packed columns are fabricated from glass or metal tubes (1–8 mm i.d.). They are designed to hold solid packing and range from 2 to 20 m in length.
- Solid support for packed columns. Most common supports are derived from diatomaceous earths such as firebrick and kieselguhr. Firebrick, which is sold under trade names such as Chromosorb P™, C22 and Sterchamol, has the better strength and larger specific surface area ($\sim 4\ m^2\ g^{-1}$). Its disadvantage lies in the fact that it is more active and hence cannot

Figure 6 Schematic diagram of GC system.[53]

be employed with polar compounds. Kieselguhr is more fragile than firebrick and has a smaller surface area ($\sim 1\,m^2\,g^{-1}$) but is less reactive. It is sold under trade names as Chromosorb W™, Celite™, Embacel™, Celatom™, Fluoropak 80™, Teflon 6™, Columpak T™, etc.

- Liquid phase. The different compounds used for analysis are Ethofat 60/25, a polyoxyethylene monostearate containing an average of 15 ethylene oxide units *MW* 938). Other substances investigated are sorbitol, diethylene glycol, mannitol hexaacetate, sucrose octaacetate, Carbowax 6000, Apiezon N and Lac 296 (polyethylene glycol succinate). All substrates are loaded to 10 wt% on the fluorocarbon supports and to 20 wt% on chromosorb supports.

Detectors.

- Thermal conductivity detection (TCD). TCD is based upon changes in the thermal conductivity of the gas stream, measured using a device called a katharometer. TCD detectors are simple, rugged, inexpensive, nonselective, accurate and nondestructive of the sample.
- FID. When compounds are pyrolyzed at the temperature of a H_2/air flame they produce ionic intermediates that provide a mechanism by which electricity can be carried through the flame. The electrical resistance of a flame is very high ($10^{12}\ \Omega$) and the resulting currents are, therefore, minuscule, so an electrometer must be employed for their measurement.
- Electron capture detection (ECD). With electron capture detectors the effluent from the column is passed over a β-emitter such as Ni-63 or tritium (adsorbed on platinum or titanium foil). An electron from the emitter causes ionization of the carrier gas (N_2) and production of a burst of electrons. In the absence of organic species a constant current between a pair of electrodes results from this ionization process. The current decreases, however, in the presence of organic molecules that tend to capture electrons. The response is nonlinear unless the potential across the detector is pulsed. ECD devices are highly sensitive and possess the advantage of not altering the sample significantly.

Reagents. A test solution is prepared from paraformaldehyde, formalin or formalin plus butanol.[37] A formaldehyde standard solution containing 23.83% formaldehyde is prepared by boiling paraformaldehyde in distilled water. The solution is filtered and its formaldehyde content is determined by the standard peroxide method. This solution is used to determine the sensitivity for formaldehyde.

Formalin solution used for the calibration is prepared by diluting previously analyzed formalin with distilled water. A standard reference solution is prepared containing 15 wt% methanol, 47.4 wt% water and 37.6 wt% butanol for routine use as reference.

Figure 7 Gas chromatograms of the test and reference solutions. Conditions: column, 5 meter Ethofat 60/25, 10 wt% on columnpak T, column temperature 115 °C, injector temperature 250 °C. flow 43 mL min^{-1}, bridge current 230 mA, sample size 5 µL. peaks: (1) methanol, (2) water, (3) formaldehyde, (4) butanol. (Reprinted with permission from Bombaugh and Bull.[37] Copyright 1962 American Chemical Society.)

Analytical Procedure. Chromatograms of the test and of the reference solutions are prepared under the operating conditions described in Figure 7, and the areas of the peaks of interest are determined with a polar planimeter or integrator. The peak areas are corrected using Equation (1):

$$A_c = A_m \frac{S_0}{S_m} \tag{1}$$

where A_c = corrected peak area, A_m = measured peak area, S_0 = peak area of reference at time of calibration, and S_m = peak area of reference at the time of analysis.

The corrected peak areas are used to determine the mass G of each component in the test solution according to Equation (2):

$$G = \frac{A_c - b}{m} \tag{2}$$

where b = intercept determined at the time of calibration, and m = slope of calibration line. Equations (1) and (2) can be combined to give Equation (3):

$$\% \text{ of component present} = \frac{[(A_m(S_0/S_m)) - b]100}{m/g} \tag{3}$$

where g = grams injected.

6.2.4.2 Derivatization Approaches Requiring Chromatographic Separation A major concern for formaldehyde analysis is the stability of the sample on the sampling media.[54] Derivatization of the compounds either in the sampling device or immediately after collection has improved the stability of samples for many methods. The most commonly used derivatives are 2,4-DNPH and pentafluorophenyl hydrazine (PEPH).

Figure 8 Gas chromatogram of a mixture of 2,4-dinitrophenyl hydrazones of carbonyl compounds. Conditions: column 4 ft × 6 mm o.d. × 2 mm i.d. glass column, packed with 2% OV liquid phase on chromosorb WAW DMCS (80–100 mesh). Flow rate of argon : methane (95 : 5) mixture 65 mL min^{-1}. Selim, 'Separation and Quantitative Determination of Traces of Carbonyl Compounds as their 2,4-Dinitrophenylhydrazones by High-pressure Liquid Chromatography', 271–277, Copyright 1977, with permission from Elsevier Science.)

The principle and analysis procedure for formaldehyde using derivatization are same as in the direct chromatography method. In derivatization methods FID is used as the detection method.[22] The preparation of derivatives is described here.

Preparation of 2,4-Dinitrophenyl Hydrazone Derivatives. 2,4-Dinitrophenyl hydrazones of formaldehyde are prepared by shaking 100 μL of formaldehyde with 100 mL of a saturated solution of 2,4-DNPH in aqueous 2 N HCl and allowing the mixture to stand at room temperature overnight. The precipitate formed is isolated, washed with 2 N HCl and water and dried over silica gel in a vacuum desiccator. The derivative formed is pure enough for GC analysis and typical gas chromatograms (Figure 8) were recorded using the conditions listed in Table 3.[22]

Preparation of Pentafluorophenyl Hydrazine Derivatives. PEPH derivatives are prepared from 0.5 mL of formaldehyde and 0.5 mL of PEPH (1.5 mg mL^{-1}) and one drop of 0.6 M phosphate buffer (pH 7.0) in 10-mL centrifuge tubes by mixing and allowing to stand for 20 min at room temperature.[56] The reaction mixture is then saturated with NaCl and one drop of 18 N H_2SO_4 and extracted with 0.2 mL of ethyl acetate containing 50 μg of *p*-xylene dichloride as internal standard. The extraction is carried out at room temperature. The excess NaCl and the aqueous layer are removed with the aid of syringe with a long needle and dried by adding a small amount of sodium sulfate. An aliquot in ethyl acetate is then applied onto the GC column. The GC conditions are as follows: 2-m glass column packed with 3% XE-60 on 80–100 mesh Celite™ 545, column temperature 120 °C, detector FID temperature 150 °C, injection temperature 150 °C and chart speed 0.25 cm min^{-1} (Figure 9).

Figure 9 Gas chromatogram of some carbonyl compounds as their pentafluorophenyl hydrazones. Conditions: 3% XE-60, 2.0 m glass column, temperature programmed from 105 to 130 °C at 2 °C min^{-1}, FID. Peaks: (1) formaldehyde, (2) acetaldehyde, (3) acetone, (4) isobutylaldehyde, (5) diethyl ketone, (IS) *p*-xylene dichloride, (6) methyl isobutyl ketone. (Reprinted from *J. Chromatogr.*, **176**, K. Kobayashi, M. Tanaka, S. Kawai, T. Ohno, 'Gas Chromatographic Determination of Low-Molecular Weight Carbonyl Compounds in Aqueous Solution as their Pentafluorophenylhydrazones', 118–122, Copyright 1979, with permission from Elsevier Science.)

6.2.4.3 Gas Chromatography/Mass Spectrometry

The gas chromatographic analysis of derivatives is tedious, requiring chemical reaction, extraction and concentration steps. An interesting approach is the gas chromatography/mass spectrometry (GC/MS) method for the analysis of formaldehyde in air. This method has the advantage of sensitivity and selectivity.[38]

Principle. GC/MS is based upon mass fragmentation techniques, with an initial trapping of formaldehyde on an adsorption tube filled with the molecular sieve 13X. The collected samples are thermally desorbed onto the analytical column (Porapak T) for separation, and then

quantified by mass fragmentography (*m*/*z* 29 and 30). Advantages of the technique include parts-per-billion sensitivity and selectivity and quantitative recovery.

Apparatus. A GC/MS instrument[38] equipped with a mass fragmentation function is used to perform the analysis. A schematic diagram of the GC/MS instrument is shown in Figure 10. The system contains a two-way valve to switch over the carrier gas and block heater for desorption of the sample from the adsorption tube.

- Adsorption tube. A 1 g amount of the molecular sieve 13X is packed into a Pyrex™ tube (15 cm × 4.5 mm i.d.) to form a bed ca. 10 cm long and the tube is secured at both ends with glass wool plugs. Prior to use, the tubes are conditioned by heating at 330 °C overnight and passing nitrogen gas through at a flow rate of 30 mL min^{-1}. The nitrogen gas is purified carefully by passing it through a molecular sieve trap in dry ice–ethanol (−72 °C) in order to prevent adsorption of trace formaldehyde from the nitrogen gas during the cooling process.
- Reagents. A stock of formaldehyde is prepared by mixing 1.3 mL formalin (about 35% w/w formaldehyde) and 1 L distilled water. The accurate concentration of formaldehyde in the solution is determined by titration before use. Standards are made up by adding appropriate amounts of this solution to distilled water.

Figure 10 (a) Schematic diagram of GC/MS system; (b) absorption tube.[38] (Reprinted from *J. Chromatogr.*, **180**, T. Yokouchi, T. Fujii, Y. Ambe, K. Fuwa, 'Gas Chromatographic Mass Spectrometric Analysis of Formaldehyde in Ambient Air Using a Sampling Tube', 133–138, Copyright 1979, with permission from Elsevier Science.)

Analytical Procedure. Air (1 L) is drawn through an adsorption tube packed with the molecular sieve 13X by a portable pump (Charles Austen Pumps). The sampling flow rate of 100 mL min^{-1} is controlled by a needle valve. The sampled tubes are sealed with silicon rubber and GC/MS analysis is performed as soon as possible after sampling.

Chromatographic separations are accomplished on Porapak T (80–100 mesh) packed in a glass column (1.8 m × 2 mm i.d.). Desorption of the sample from the adsorbent is carried out at 240 °C with the high-purity helium carrier gas flowing at a rate of 20 mL min^{-1} for 2 min. During thermal desorption, the formaldehyde transferred onto the analytical column is temporarily trapped at the top for 2 min at a temperature of 30 °C and the carrier gas flow is then switched to the bypass. The mass fragmentograms of the *m*/*z* 29 and 30 ions are obtained by temperature programming at 16–150 °C min^{-1}. The concentration of formaldehyde in the samples is determined from the peak heights of the mass fragmentograms of the *m*/*z* 30 ion, using a calibration curve prepared from the standard solutions (Figure 11).

Measurement of Breakthrough Volume. Breakthrough volumes of adsorption tubes are measured in the following way. The elution volumes of the tubes are monitored for formaldehyde with the GC/MS system. When helium gas is flowing through the tube at room temperature (25 °C), formaldehyde vapor is injected (ca. 100 μg) onto the top of the tube, and the elution volume is taken as the product of the flow rate (20 mL min^{-1}) and the elution time from the tube (which is obtained by subtracting the retention time of formaldehyde on the GC column from the total elution time). The breakthrough

Figure 11 Mass fragmentograms of air sample. Peaks: (1) propane, (2) formaldehyde, (3) *n*-butane, (4) water peak due to excess source pressure.[38]

volume is taken as that volume of air which releases a detectable vapor (0.2 ng) from the adsorbent tube.

Calibration Curve. The calibration curve for formaldehyde is linear in the range 0–50.0 ng. The detection limit of the method is 0.3 ppb at a signal-to-noise ratio of >3.

Recovery. Recoveries for three runs with a high loading of 10 ng formaldehyde per 5 μL aqueous solution and a low loading of 1 ng formaldehyde per 5 μL solution are 101%, with standard deviations of 2 and 14%, respectively.

6.2.4.4 High-performance Liquid Chromatography

Principle. The limitations of insufficient volatility or thermal stability faced in GC analysis are not present in liquid column chromatography. A sample is introduced into the system via an injector from which it is forced by a flowing stream of solvent, often called the mobile phase, through a narrow bore transport tube to the column. The column is a large tube (2–8 mm i.d.) containing small particles (5–125 μm) known as the stationary phase. The particles alone, when held within the confines of the tubes, comprise the chromatographic bed, and a sample mixture separates as a result of different components adhering to or diffusing into the packing particles. Thus, as the mobile phase is forced through the chromatographic bed, a sample is separated into various zones of sample components, referred to as bands. The bands continue to migrate through the bed, eventually pass out of the column (elution), and pass through one or more detectors. The recorder tracing from the elution of a single band is called a peak. Peaks are usually identified by their retention time, which is the time required to elute the corresponding band from the column.

Apparatus. For isocratic operation, a standard HPLC instrument has the following components (Figure 12):[46] (1) a solvent reservoir for the mobile phase; (2) a solvent pump (or pumps) equipped with a damping unit, if a pulsating action results, to force the mobile phase through the chromatographic system; (3) a precolumn (except for bonded phases) and a guard column, the former to presaturate the mobile phase with the stationary phase and latter to prevent contamination of the separation

Figure 12 Schematic diagram of HPLC system.[53]

column; (4) a pressure gauge inserted close to the column to measure column inlet pressure; (5) a sampling or injection device to introduce the sample into the column; (6) the separation column; and (7) a detector with recorder readout or other data handling device.

Derivatives that absorb strongly in UV light have been prepared for HPLC. The method commonly used to determine traces of formaldehyde is to form the 2,4-dinitrophenyl hydrazone and determine the derivative by HPLC. However, for C_1-C_5 aldehydes 2,4-dinitrophenyl hydrazones have been synthesized and successfully separated by adsorption chromatography. Selim[55] reported the separation of 2,4-dinitrophenyl hydrazones of aldehydes by using reversed-phase HPLC. Beasley et al.[39] reported a new solid sorbent silica gel coated with 2,4-DNPH for formaldehyde. Analysis of the resulting hydrazone derivative is done by HPLC with a UV detector.

Reagents. Reagents include formaldehyde (37%), dimethylformamide (DMF), hydrochloric acid, acetonitrile and silica gel. Paraformaldehyde permeation tubes can be purchased or α-POM permeation tubes can be prepared from α-POM.

The α-POM tubes or the purchased paraformaldehyde permeation tubes can be used successfully to generate a dynamic formaldehyde standard in air.

The 2,4-DNPH reagent is prepared by adding 0.25 g of 2,4-DNPH to 100 mL of 6 N HCl.

The 2,4-DNPH coated silica gel is prepared as follows. The mixture of 2,4-DNPH in DMF is unstable and must be used quickly. DMF is used because of its superior solvent properties. Silica gel (12.5 g) is placed in a 100-mL round-bottom flask with by 12.5 mL of 6 N HCl. DMF (40 mL) is added to a 100-mL volumetric flask containing 5.0 g 2,4-DNPH. This mixture is swirled for 10–15 s, quickly diluted to the mark with additional DMF and immediately poured through a glass wool plug into the flask containing the silica gel and HCl. The volumetric flask and glass wool are rinsed with an additional 5 mL of DMF, which is also added to the round-bottom flask. The mixture is allowed to stand for 30 min, with occasional swirling, before isolation by vacuum filtration. The coated silica gel may be rinsed sparingly with DMF (2–3 mL). Excessive washing will result in increased capacity for formaldehyde. It is left on the filter paper with continued suction for 1–2 min and then transferred quickly to a 100-mL round-bottom flask. It is dried under vacuum at 55 °C for 1 h with brief turning every 10 min.

The collection device is a glass tube (10 cm × 4 mm i.d. × 6.2 mm o.d.) containing a 300-mg front section and 75-mg backup section of the coated silica gel. The two sections are separated by small plugs of glass wool. Tubes prepared as described here are found to have a pressure drop of 52 kPa in H_2O at a flow rate of 115 mL min^{-1}. They have a capacity of ~123 μg formaldehyde (5 ppm for a 20-L air sample) before significant breakthrough occurs, regardless of humidity.

Air Sampling. Sampling is done by connecting the sampling tube to the Dupont pumps. Formaldehyde loadings are varied by time of collection with constant permeation and flow rates. Typically, the output of the permeation device is set for 1.0 ppm and is sampled at 100–200 mL min^{-1}.

Analysis. The front section of the collection tube, including the front glass wool plug, is transferred to a 1.8-g vial containing 2.0 mL acetonitrile. The backup section and the glass wool plug that separates the two section are treated similarly. The vials are stoppered with polypropylene caps (no Bakelite) and allowed to stand overnight.

For analysis 0.2 mL of the desorbing solution is injected in the loop filter port to provide flushing and loading of the 50 μL injection volume. The system also is flushed with acetonitrile between injections. The mobile phase for the analysis is 65 : 35 (v/v) water : acetonitrile, pumped at 2.0 mL min^{-1}. A typical chromatogram is shown in Figure 13. Quantitation of this work is done by peak height/peak area using a calibration curve generated from a series of the standards containing 10–400 μg mL^{-1} authentic formaldehyde 2,4-dinitrophenyl hydrazone in acetonitrile (corresponding to 0.1–4.6 ppm formaldehyde in air for a 20-L sample). Beasley et al.[39] validated this method over the range 2.5–95 μg of formaldehyde with 94% recovery and relative standard deviation ±0.04.

Figure 13 HPLC chromatogram for injection of 4.6 μg of formaldehyde-2,4-dinitrophenyl hydrazone (equivalent to 1.08 ppm formaldehyde in air, for a 20-L air sample). (Reprinted with permission from Beasley et al.[39] Copyright 1980 American Chemical Society.)

DNPH derivatization followed by HPLC analysis involves pre-column reactions which may be affected by other components in the sample. In addition the resultant signals, absorptivities and conductivities are sensitive to matrix effects. Igawa et al.[57] have developed an analytical procedure that couples HPLC with a segmented flow analyzer which involves a post-column reaction. Formaldehyde was separated on a reversed-phase C_{18} column derivatized with MBTH and detected at 640 nm.

3-Methyl-2-benzothiazole Hydrazone Derivative. The aldehydes which were separated on the reversed-phase C_{18} column are derivatized with MBTH and detected at 640 nm.

The eluent is an acetonitrile–water mixture prepared from HPLC-grade acetonitrile and purified deionized water.

The reagents used in the reaction detector are MBTH (0.5% w/v), Fe^{3+} solution and Triton X-100. MBTH is prepared by dissolving 3-methyl-2-benzothiazolidone hydrazone hydrochloride monohydrate in water to form a 0.5% (w/v) solution. $FeCl_3$ is prepared by dissolving $FeCl_3 \cdot 6H_2O$ in 0.01 M HCl (10% w/v). Triton X-100 is prepared by diluting with water to 0.1% (v/v).

The HPLC apparatus is coupled with a rapid flow analyzer. The HPLC apparatus is equipped with a reversed-phase C_{18} analytical column and an adsorbosphere C_{18}. A guard column is connected just before the analytical column, and there is a stream tubular reactor.

The sample is injected by a variable volume injector. The separation of aldehyde is performed with isocratic elution using a 40:60% or 1:99% by volume acetonitrile:water mixture. The flow rate and the column temperature are maintained at 0.5 mL min^{-1} and 30 °C, respectively. Post-column reaction occurs at the stream tubular reactor. Absorbance of the colored solution is measured intermittently at 640 nm using the bubble gate of the analyzer. The pathlength is 1 cm. The signal is recorded on a chart and concentration is measured from the peak height or peak area, as determined by the integrator (Figure 14).

Calibration is based on comparison of the sample peak height with those obtained by injecting a mixture containing a known concentration of formaldehyde with a 1% acetonitrile–water eluent.

6.2.4.5 Ion Exchange Chromatography IEC is an analytical method combining formaldehyde collection on an oxidizer impregnated with charcoal with subsequent IC analysis of the formaldehyde as formate ions. It has been developed by Kim et al.[40]

Principle. The essential principle of this technique is an ion exchange process between the mobile phase and the exchange group covalently bound to the stationary phase. The exchange function in anion chromatography is generally a quaternary ammonium base. During the chromatographic process, the counter-ion of the exchange function is exchanged for the sample ion, and for a short time the latter becomes attached to the fixed charge on the resin. Due to variations in the affinities of the species being chromatographed for the stationary phase, a separation of the various sample components is possible.[58]

Figure 14 HPLC chromatogram of C_1–C_6 carbonyls. Conditions: Spherisorb ODS-2 (5 μm), 4.6 × 250 mm, injection volume 20 μL, eluent 40% acetonitrile + 60% water. Peaks: (1) 25 μM HCHO, (2) 50 μM CH_3CHO, (3) 75 μM C_2H_5CHO, (4) 100 μM C_3H_7CHO, (5) 150 μM C_4H_9CHO, (6) 200 μM $C_5H_{11}CHO$. (Reprinted with permission from Igawa et al.[57] Copyright 1989 American Chemical Society.)

Any substance that has a retention time coinciding with that of formate will interfere. A high concentration of any one ion also interferes with the resolution of others but sample dilution overcomes many interferences.

Apparatus. An ion chromatograph (Figure 15) includes an injection valve, a sample loop, an AG4A guard column, an AS4A separator, a self-regenerating suppressor column, a temperature-compensated small volume conductivity cell (4 μL) and a recorder capable of full scale response of 2 s or less. An electronic peak integrator is optional. The ion chromatograph should be capable of delivering 2–5 mL eluent min^{-1} at a pressure of 9.65–13.8 MPa.

Reagents. Deionized or distilled water is free from interferences at the minimum detection limit of each constituent. The eluent solution is 5 mM $Na_2B_4O_7 \cdot 10 H_2O$ (borax). Standard solution (100 mg L^{-1}) contains 1.410 g sodium formate dissolved in 1 L water and stored

Figure 15 Schematic diagram of ion exchange chromatograph.[58]

in plastic bottles in a refrigerator. The working solution (1 ppm) contains 1 mL of standard solution diluted to 100 mL.

Procedure. The air is passed through a solid sorbent tube (4 mm i.d. × 7 cm long) containing 150 mg of impregnated charcoal at 50–200 mL min^{-1} for 3–5 h. The charcoal is removed to a tube containing 15.0 mL of 0.1% H_2O_2 and shaken for 1 h, then sonicated for 20 min. The solution is filtered through a 0.45-μm membrane filter and the sample is injected into an ion chromatograph.

After turning on the ion chromatograph the eluent flow rate is adjusted to 2 mL min^{-1} and the system is allowed to equilibrate for 15–20 min. A stable baseline indicates equilibrium conditions.

Calibration. The approximate retention time of the standard is determined (Figure 16). Concentrations are calculated based upon peak areas of standard that are prepared daily from 100 ppm stock solution. The stock solutions are prepared weekly from the sodium salt of formic acid, spiked with $CHCl_3$ and stored at 4 °C. Typically standard concentrations are in the range 0.1–1 ppm. The standards are run in triplicate. After every five samples the standard is run to check peak response, and if deviation is more than 2% the system should be recalibrated.

Figure 16 Chromatogram showing determination of formaldehyde as formate ion.[40]

The analytical precision is determined by running the 1 ppm standards nine times, and is found to be 1.64%.[49]

Sample Analysis. The sample is injected into the ion chromatograph and the peak height/peak area and retention time are recorded.

Calculation.

$$C = HFD$$

where C = mg formaldehyde L^{-1}; H = peak height/area, F = response factor = concentration of standard/height (area) and D = dilution factor for those samples requiring dilution.

Figure 17 Nondispersive Luft type IR gas analyzer. A = amplifier, C_s, C_r = Luft detector cells for sample and reference beams, Ch = chopper, D = thin metal diaphragm, M = mirrors curved to focus beam from source S on to windows W of suitable IR-transparent material, P_s, P_r = fixed plates of double capacitor P_s–D–P_r.[61]

6.2.5 Infrared Spectroscopy

Infrared (IR) gas analyzers depend for their operation upon the fact that some gases and vapors absorb specific wavelengths of IR radiation. The technique uses a conventional double beam IR spectrometer system with a pair of matched gas cells in the two beams. One cell is filled with a reference gas, which is a non-absorbing gas like nitrogen, while the measuring cell contains the sample. The difference in optical absorption detected between the two cells is a measure of the absorption of the sample at the particular wavelength. The selectivity of this technique is high because of characteristic absorption spectra corresponding to the difference in vibrational energy levels of the bands. Thomson and Keller[59] and Zeller[60] have compiled and published IR spectra of hazardous gases and vapors. Aliphatic aldehydes show strong absorption near 1730 cm^{-1} (5.75 μm) (1740–1720 cm^{-1} region) due to C=O stretching. C–H stretching absorption [2825, 2717 (3.54, 3.68 μm)] is seen in the 2830–2695 cm^{-1} (3.53–3.71 μm) region. Two moderately intense bands are frequently observed in this region. The appearance of two bands is attributed to Fermi resonance between the fundamental aldehyde C–H stretching and the first overtone of the aldehyde C–H bending vibration that usually appears near 1390 cm^{-1} (7.20 μm).

6.2.5.1 Nondispersive Infrared Analysis Long-path IR techniques usually involve long cylindrical glass cells (about 5 cm diameter and 100 cm length) filled with gases and end windows of NaCl (transparent down to 650 cm^{-1}), KBr (transparent down to 400 cm^{-1}) or CaF_2 (transparent down to 1250 cm^{-1}). CaF_2 is the most resistant to attack by water but is also much more easily chipped or cracked. In a nondispersive infrared (NDIR) spectrometer the IR radiation from the source is not dispersed according to wavelength by a prism or grating as in a standard IR spectrometer. It is made very specific for a given compound or type of compound by using the material under investigation as part of the detector. The detector is efficient in that it ''sees'' all the wavelengths of interest simultaneously. It is also selective in that interference by another gas at one particular wavelength will be minimized because it is not present at most other wavelengths.[61]

This is the basis of the Luft nondispersive detector shown in Figure 17. Light is split along two paths: in one is a reference cell filled with clean air, in the other is the sample of contaminated air. The detector consists of two sealed chambers filled with the same (pure) gas which is to be determined in the air sample. As less radiation reaches the area C_s, the pressure increase is less than in C_r, so the flexible metal diaphragm D is bent towards the plate P_s of the differential capacitor P_r–D–P_s. The chopper then cuts off radiation from both halves and the pressure differential falls off. The output is a series of pulses, the height of which increases with increasing formaldehyde concentration.

6.2.5.2 Fourier Transform Infrared Spectroscopy In FTIR instruments, the IR spectra are more accurately and more readily obtained in a matter of seconds using the

Figure 18 Schematic diagram of FTIR spectrometer. IRSO = IR source and optics, IIRB = incident IR beam, MM = movable mirror, CP = compensator, BS = beam splitter, FM = fixed mirror, SP = sample, TB = transmitted beam, DT = detector, IFS = interferogram signal, IF = interferogram, IN = intensity, PD = path difference, CT = computer, PT = %transmittance, IRSD = IR special display.[62]

Figure 19 Schematic diagram of an FTIR system used in ambient air studies.[24]

mathematical technique called Fourier transformation. Figure 18 shows the schematic diagram of an FTIR instrument.[62] An interferogram is generated as the mirror moves, and the path difference between the two beams changes. The Fourier transformation of the interferogram is done by a computer to decode it and produce the IR spectrum.

Since all wavelengths of IR spectra are measured simultaneously, the method is several times faster than with dispersive instruments. As slits and gratings are not used, the full IR energy is available to be sent through the sample (high energy throughout) so that even a trace of the sample is adequate. This technique is sensitive down to 20 ppb formaldehyde in air and is ideal for determining vehicle emissions. Measurement of formaldehyde by FTIR has been reported by Scott Research Laboratories,[6] Tuazon et al.,[24] Haack et al.,[63] and Lawson et al.[34] Figure 19 is a schematic diagram of an FTIR system used to monitor pollutants in ambient air. The eight mirror system shown in Figure 19 was exploited by Tuazon et al.[24] in measurements over a period of five years in the Los Angeles basin. The 22.5-m path multiple reflection cell shown afforded a total pathlength in excess of 1 km.

6.2.5.3 Fourier Transform Infrared Spectroscopy for the Measurement of Formaldehyde in Vehicle Exhaust

Measurement of formaldehyde in vehicles exhausts is described here following the method developed by Haack et al.[63]

Apparatus. The general set-up used for vehicle exhaust analysis is depicted in Figure 20. The constituents are a vehicle chassis dynamometer, dilution tunnel and FTIR apparatus connected as shown. The vehicle tailpipe is connected to a 7.6 m × 30.5 cm i.d. dilution tunnel via an insulated pipe. Pure, dry air is used as the diluent for vehicle exhaust. Dilution ratios from 7 : 1 to 10 : 1 are used depending upon the anticipated levels of formaldehyde generated by each test vehicle. The dilution of the exhaust ensures that condensation of water does not occur in the unheated FTIR apparatus.

Fourier Transform Infrared Sampling System. The FTIR sampling system is shown in Figure 21. The sample is drawn from the dilution tunnel through an unheated 45.7 m × 0.95 cm i.d. line made of Teflon™ and hence through the Wilks cell of the FTIR apparatus by means

Figure 20 Sampling apparatus for vehicle exhaust analysis. (Reprinted with permission from Haack et al.[63] Copyright 1986 American Chemical Society.)

Figure 21 FTIR sampling system. (Reprinted with permission from Haack et al.[63] Copyright 1986 American Chemical Society.)

of a rotary vane pump at a flow rate of 25 L min^{-1} (10 s lag time). The sample in the cell remained at room temperature, while the pressure was maintained at 93 kPa by using a metering valve between the cell and the rotary vane pump. The sample is filtered at the dilution tunnel through a 142-mm diameter quartz fiber filter in a stainless-steel holder at room temperature. The filter holder is heated to 55 °C for diesel-fueled vehicle experiments. The purpose of the filter is to prevent particulate matter from entering and contaminating the FTIR sample line and cell.

Fourier Transform Infrared Spectrometer. As described previously, FTIR spectrometers differ from conventional grating or prism instruments in that wavelength determination is accomplished by modulating each wavelength at its own unique audio-range frequency via a scanning Michelson interferometer. The digital interferogram is frequency analyzed (Fourier transformed) to produce the IR spectrum. The sample cell used is a custom gold-coated Wilks 20-m variable path cell, used in 14th order with an effective pathlength of 21.75 m. A HgCdTe detector exhibiting negligible nonlinearity is used. An absorbance spectrum is generated by calculating the logarithm of the ratio of the corrected spectrum of the tunnel dilution air to the corrected sample spectrum.

The formaldehyde IR signal is measured by integrating the absorbance of selected vibration–rotation lines in the C–H stretching region from 2739 to 2827 cm^{-1}. Figure 22 displays the FTIR formaldehyde spectra of a standard and a methanol-fueled vehicle exhaust sample. The exhaust spectrum is generated from one interferogram. By using this standard the formaldehyde diluted exhaust concentration is determined.

6.2.6 Fluorimetric Method

Most of the in situ techniques described earlier require several minutes to several hours to collect sufficient amounts of the samples, depending on the ambient formaldehyde concentration. These techniques have higher detection limits (ppm or ppb) and therefore cannot be used for in situ measurements where formaldehyde occurs in parts per trillion by volume concentration ranges. Fluorimetric determination of formaldehyde in

Figure 22 FTIR formaldehyde spectra in nitrogen and in diluted methanol-fueled vehicle exhaust. (Reprinted with permission from Haack et al.[63] Copyright 1986 American Chemical Society.)

air has been discussed by Lazrus et al.,[28] Heikes,[10] Heikes et al.,[64] and Dong and Dasgupta.[65] A fluorimetric method based on diffusion of atmospheric formaldehyde vapor to an enzyme-coated piezoelectric crystal detector[28] has been developed for automated fluorimetric determination of formaldehyde in air. The unique advantage of enzyme catalysis for atmospheric measurements is the ability of many enzymes to react selectively with a single species within a complex mixture of compounds. The automated instrument consists of device for continuous rapid transfer of formaldehyde vapor from the sample air to water, a peristaltic Technicon Auto Analyzer pump and a fluorometer fitted with a flow cell to analyze the aqueous formaldehyde.

The dissolved formaldehyde reacts reversibly with H_2O to form the dihydroxymethane adduct which is the dominant form in solution. The $CH_2(OH)_2$ reduces nicotinamide adenine dinucleotide (NAD^+) to its fluorescent form (NADH), a reaction which is catalyzed by formaldehyde dehydrogenase (FDH). The suggested overall reaction mechanism is shown in Schemes 13 and 14.

$$CH_2(OH)_2 + FDH \longrightarrow HCOO^- + H^+ + H_2FDH$$

Scheme 13

$$H_2FDH + NAD^+ \longrightarrow NADH + FDH + H^+$$

Scheme 14

The automated technique is free of interferences from common atmospheric constituents, sensitive and relatively fast. The detection limit is 120 pptv. The calibration curve is linear to approximately 100 ppbv. The coefficient of variation is 2% at 20 ppbv formaldehyde. The rise time of the signal from 10 to 90% is 80 s.

6.2.6.1 Reagents Stock standard solution (0.01 N) is made by dissolving 0.30 g of paraformaldehyde in water (1 L), which is standardized volumetrically as described previously.

Formaldehyde vapor standards are generated by equilibrating air with aqueous formaldehyde standard. The standard generator apparatus (Figure 23) consists of a tube lined with glass-fiber filter paper. A liquid formaldehyde standard runs down the filter while air

Figure 23 Vapor phase standard generator. Typical air flow rate is $<1\,L\,min^{-1}$. (Reprinted with permission from Lazrus et al.[28] Copyright 1988 American Chemical Society.)

supplied by a pure air generator runs in a counter current flow. The tube is thermostatted (usually at 18 °C). Dilution of this air to yield the desired concentration of formaldehyde occurs in the test manifold. The coefficient of variation for the difference between calculated and observed formaldehyde in vapor phase standards ranging between 1.8 and 4.4 ppbv is 10.3% ($n = 11$) resulting principally from errors in gas flow control and dilution. No wall losses are detected when using an inlet of PFA (polyfluoroalkene) tubing, with 0.64 cm i.d. and 3 m length. To set the instrument at zero, formaldehyde is initially removed from incoming air by passing it through a molecular sieve trap which is 25.4 mm i.d. and 152.4 mm long. The molecular sieve is 13X (0.32 cm pellets). The efficiency of the molecular sieve trap appears to decline too quickly for it to be useful as a zeroing device in this application. To irreversibly bind formaldehyde, a trap constructed of PFA Teflon® (4 cm i.d., 6 cm long) was filled with silica gel coated with 2,4-DNPH[39] The collection efficiency, at 1.0 L min^{-1}, is 97% for 7.0 ppbv formaldehyde. When clean air is sampled (0.1–2.0 ppbv formaldehyde), two additional techniques can be used for stabilizing the instrument to zero. The first is simply to use ''zero'' air free of formaldehyde. The second is to use the reagent blank as the zero signal. The reagent blank is obtained by allowing the scrubbing solution to bypass the air scrubbing coil. The use of ''zero'' air and the reagent blank yield identical signals and are believed to be the most reliable means of zeroing the instrument at a very low concentration of formaldehyde.

To prepare the FDH reagent, FDH from *Pseudomonas putido* in the form of lyophilized powder is dissolved in water (16 enzyme units per 100 mL) (one enzyme unit oxidizes 1.0 μmol of formaldehyde to formic acid per minute at pH 7 and 30 °C). This reagent is buffered at pH 8 with 0.01 M Na_2HPO_4.

To prepare the NAD^+ reagent, 35 mg of 99+% crystalline β-NAD is dissolved in 100 mL water (approximately 5×10^{-4} M). The pH is adjusted to 4–5 with HCl for stabilization.

6.2.6.2 Experimental Formaldehyde vapor is stripped from the atmosphere by means of concurrently pulling the air sample and scrubbing water through a 28-turn 3 mm i.d. Technicon Auto Analyzer mixing coil (Figure 24). The scrubbing water is adjusted to pH 2.0 with hydrochloric acid and nominally flows at 0.42 mL min^{-1} through the coil. Air is sampled at 1.0 L min^{-1} giving a residence time of about 0.3 s. The scrubbing water, which is impelled by the air as it flows through the vertical coil, forms a thin film on the glass surface, providing a large surface for gas exchange. For maximum accuracy, the delivery rate of the pump tube introducing water into the scrubbing coil is calibrated.

Figure 24 Pyrex™ glass stripping coil and separator. Typical flow rates are 1.0 L min^{-1} for air and 0.42 mL min^{-1} for scrubbing water. (Reprinted with permission from Lazrus et al.[28] Copyright 1988 American Chemical Society.)

The aqueous formaldehyde is isolated from the scrubbing air in a vertical separator column by gravity. It is then mixed with buffer (0.2 M Na_2HPO_4 adjusted to pH 8 with HCl) and led into a five-turn mixing coil. The FDH and NAD^+ are then added to the reaction stream, followed by a second five-turn mixing coil. The reaction mixture is pumped through a reaction time delay coil (13.2-min delay) to allow production of NADH to completion (Figure 25). A filter is placed in the enzyme line downstream of the pump to remove particles occasionally seen in this reagent. The polycarbonate filter (8.0 μm pore size and 13 mm diameter) is contained in an in-line polycarbonate filter holder. The bubbles are removed from the flow stream by a Technicon debubbler placed immediately upstream of the fluorometer flow cell.

6.2.7 Tunable Diode Laser Absorption Spectroscopy

TDLAS is a technique based on IR absorption spectroscopy. Unlike FTIR this technique relies on measuring the absorbance at specific wavelengths due to absorption of IR radiation by various pollutants. However, rather than using a continuous wavelength light source and scanning the entire IR spectrum, TDLAS employs a laser light source of very narrow linewidth which is tunable over a smaller (300 cm^{-1}) wavelength range.[5]

The very high spectral resolution of the lasers allows the measurement of single rotational vibrational lines in the spectrum of the target molecule which leads to excellent specificity. Moreover, the method is highly

Figure 25 Schematic diagram of the automated fluorometer. (Reprinted with permission from Lazrus et al.[28] Copyright 1988 American Chemical Society.)

sensitive and allows for a very good time resolution. The method is therefore suitable for sampling from aircraft or for the detailed study of temporal variations of photochemically related species and for validating photochemical models of the troposphere in the remote troposphere, particularly where accurate measurements are needed. TDLAS is more useful for following specific pollutants known to be present than for searching for previously unidentified species. Many workers[25,66–69] have discussed different types of tunable IR laser sources used in absorption spectroscopy for monitoring of pollutants. Tuning of the emitted wavelength of the diode can be accomplished through variation of one of three possible parameters: applied magnetic field strength, diode temperature and hydrostatic pressure. Temperature, which can be controlled by changing the current through the diode, is the most commonly used.

Several different modulation techniques can be used to increase the signal-to-noise ratio. For example, the laser beam can be mechanically chopped and detected using phase-sensitive detection with a lock-in amplifier. A more commonly used method for accurately measuring small absorbances is to modulate the frequency output of the laser by modulating the current and thus the temperature of the diode.[70] Absorbances down to 10^{-5} M can be measured, corresponding to ppb to sub-ppb concentrations at a pathlength of 40 m (e.g. using white cell optics) for many pollutants of atmospheric interest.

The Doppler limited C–H stretching spectrum in the 2700–3000 cm^{-1} region (3.3–3.5 μm) or functional group (carbonyl group) absorption in the 1740 cm^{-1} (5.6 μm) region is used for monitoring of formaldehyde. A continuous wave (CW) difference frequency spectrometer, which operates by mixing on argon ion laser with a tunable dye laser in a non-linear optical crystal ($LiNbO_3$), is used for monitoring formaldehyde in the 3.5-μm region. Pine[67] constructed this type of laser source, which operates in the 2.2–4.2 μm region and achieved a tunable IR output with microwatt power at a resolution of 0.001 cm^{-1}.[71–73]

Figure 26 Schematic diagram of the TDLAS instrument. LSA = laser source assembly, M = mirror, D = detector, S = switching mirror, MV = motivated valve, RC = reference cell, P = pressure gauge, L = lens. (Reproduced from Harris et al.[25] with kind permission from Kluwer Academic Publishers.)

A white cell is used in the TDLAS system to provide the long pathlength required to attain the desired sensitivity. The sample is pumped at reduced pressure (3.33 kPa) through the white cell to reduce the overlap between absorption lines of atmospheric constituents. There is also a provision to fit the observed spectra to the known spectral properties of various gases that absorb in the spectral region of interest. A background spectrum is taken in the ambient sample after removing only the formaldehyde. The difference between the ambient and background spectra is due to formaldehyde alone. When the curve is fitted to a database of known spectra the resulting concentration is tied directly to the physical properties of the gas of interest. A calibration with known concentrations is only needed as a check on whether the sampling system efficiently passes the formaldehyde to the optical cell. Formaldehyde has been estimated using TDLAS by Harris et al.,[25] Mackay et al.,[27] Harder et al.,[8] and NASA.[74]

6.2.7.1 Instrumentation A schematic diagram of the instrument developed by Harris et al.[25] is shown in Figure 26. The instrument incorporates two laser source assemblies to enable simultaneous monitoring of two species in the same air sample, and uses line locking of the linear output frequency to the selected absorption features by microprocessor control of the laser operating temperatures. It also incorporates a data acquisition and instrument control system which permits automated operation. The laser output is frequency modulated at 7.5 kHz and synchronously detected at 15 kHz. A switching mirror, S, is first aligned to direct radiation from laser A into the white cell. The computer generates the laser output as a 2*f* spectrum.

The entrance window on the white cell is mounted at an angle of about 45° with respect to the laser beam and serves as a beam splitter. About 5% of the laser power is reflected through cells (RC1 and RC2) containing high concentrations of the monitored species to detector D. The signal from this detector is demodulated at 7.5 kHz using a phase sensitive detector whose output is compared with a dc voltage to register a reproducible point near the absorption line center on each scan. At each step

of the scan, the software checks to see if the line center has been reached. This approach allows the system to remain locked to the absorption feature while retaining the advantages of scanning the laser output across the whole absorption feature.

Data are accumulated in this manner for a period of for example 3 min, providing an average value of the 2*f* line profiles for the two species during that time. The raw data are analyzed by the program at the end of each averaging period. The analysis program first digitally smooths the data using a least squares algorithm,[75] which is very effective at removing high frequency noise without distorting the 2*f* lineshape if the smoothing window is correctly chosen. After smoothing of the ambient spectrum, either a smoothed background (zero air) spectrum or a least squares fitted low order polynomial, or both, is subtracted to suppress frequency-dependent background structures and/or residual etalon signals in the spectrum.

6.2.7.2 Linearity, Response Time, Sampling Integrity and Detection Limits To assess the relationship between the 2*f* signal and the mixing ratio, signals are measured as a function of formaldehyde mixing ratio determined by adding the output of the permeation device to various flows of clean air. No deviations from linearity are observed up to 50 ppbv.

The response time of the instrument toward changes in formaldehyde mixing ratios is investigated by setting the laser frequency to line center and recording the 2*f* peak signal amplitude as a function of time when calibration gas is suddenly added or removed from the flow at the air inlet. The results showed that the response time for a 90% change in the formaldehyde mixing ratio is a few seconds, corresponding to the residence time of the sampled air in the white cell. At these concentrations, polymerization of formaldehyde on surfaces does not occur and the monomer does not appear to interact strongly with the Teflon® surfaces of the sampling system.

The sampling integrity of the inlet system is confirmed by the observation that no differences in signal could be detected when calibration gas is introduced at the inlet of the sampling line (5 m of 6.25 mm o.d. Teflon® tubing) or directly into the white cell. Further tests compared the signals when a calibration spike is added to dry nitrogen carrier gas, to zero air or to ambient air streams. No effect on the throughput is detected. The laser is operated on individual lines in the 1740-cm^{-1} region of the formaldehyde absorption spectrum. The calibration method removes the need to assign the chosen line(s) spectroscopically or to measure their integrated line strengths. The methods used for determining the system detection limits and avoiding spectroscopic interferences are discussed by Slemr et al.[72] The minimum detectable mixing ratios are derived from reproducibility of the background spectra and low ppbv level calibration mixtures.

The detection limits achieved for formaldehyde are 0.25 ppbv using a 33.5 m optical pathlength and an averaging time of 3 min. The factors governing detection limits have been found to be a combination of random (high frequency) noise arising from the laser and the detector and slow changes (drifts) in the wavelength-dependent background structure. This structure arises because the laser power output varies when the driving current is modulated and swept across the absorption feature. Detection limits could be reduced to ~0.15 ppbv by co-addition of the 3 min spectra to form 30 min averages.

6.2.7.3 Measurement Accuracy The accuracy of the measurements is estimated to be ±20%. Determination of the output of the permeation device produces the largest source of error with the uncertainty in the colorimetric procedure assessed at ±10%. Additional uncertainties of ±2% are caused by temperature variations of the permeation device and of ±5% from the measurement of the air flow into which the calibration gas is introduced.

Sample pretreatment, the initial stages of an analytical procedure, becomes the essential stage in environmental analysis. The only method of determination of organic compounds in water which avoids the isolation and preconcentration step uses direct injection of an aqueous sample on to a gas chromatographic column. Direct aqueous injection (DAI) is the simplest method for the determination of organic water pollutants. This method is also very fast and easy to automate. The method avoids the problems associated with using solvents (toxic and expensive) and incomplete recovery of the analytes during their isolation from the aqueous phase, the effect of potential contaminants when using solvent or solid-phase extraction (SPE), and losses of the analytes during the enrichment step.

The idea of DAI on to a chromatographic column is very old and for liquid chromatography and ion chromatography was widely applied from the beginning of these techniques. In the beginning of the application of this technique in gas chromatography (GC), packed columns were used. The real issue for the development of GC and the application of DAI is connected with introducing to practical use a capillary column with a polar or nonpolar stationary thin liquid film or thin layer. The next, very important step was to introduce a direct injection oncolumn, which eliminates a lot of problems connected with injection in the split or splitless mode.

The determination of haloforms in water using DAI on to a capillary column and electron capture detection (ECD) was the most spectacular application of this method. The DAI/GC/ECD method was used for determination of haloorganic compounds in the different aqueous samples (tap, surface, swimming pool, and seawaters, beers, juices, soft drinks, and physiological liquids). This method was also used for the determination of semivolatile and nonvolatile haloorganic and other organic compounds in the different aqueous samples.

1 INTRODUCTION

Water, the substance so vital to humans and their well-being, the source and basis of life on earth, has recently become a serious danger to our health and life and to the life and health of flora and fauna. Furthermore, desertification of large areas of the world is now observed, and water, particularly clean water, is rapidly becoming a highly desirable and increasingly expensive commodity. Intensive industrialization of the world has resulted in an increased input of toxic inorganic and organic compounds to waters, drastically reducing the quality of surface waters which are a source of drinking water for a large part of the world population. Groundwater supply, which is basically nonrenewable, is diminishing and, in addition, anthropogenic groundwater pollution has become a fact of life. A majority of anthropogenic

water pollutants are toxic compounds, dangerous not only to humans but also to animals and plants. Consequently, there is a need for continuous monitoring of the degree of pollution of potable and surface waters by anthropogenic inorganic and organic compounds. Excessive concentrations of pollutants, above maximum contaminant levels, not only warn consumers but also signal the existence of uncontrolled discharge of wastes, improperly operating treatment plant, lack of enforcement of legislation dealing with water management, or other violations of environmental laws. In order to be able to monitor environmental pollutants properly and effectively, analysts should have a variety of methods of isolation and determination of these contaminants, taking into account both physico-chemical properties of individual compounds and groups of compounds in addition to characteristics of matrices in which these compounds occur.

A majority of organic compounds in water are of natural origin. This is a large and diversified group of mostly unidentified compounds such as humic and fulvic acids, tannins, peptides, and amino acids. Their total concentration varies from 0.1 mg L^{-1} for groundwater, through 1–5 mg L^{-1} for most surface waters, to 20–25 mg L^{-1} for some waters with the highest concentrations of organic matter.[1,2] These compounds are predominantly nontoxic, but can be precursors of toxic compounds in the process of water treatment.

Anthropogenic organic compounds present the main hazard to the life and health of humans and flora and fauna. The number of known organic compounds is now estimated to be about 16 million, 2 million of which are compounds produced by synthesis alone. Every year, approximately 250 000 new compounds are synthesized and about 1000 of these are manufactured on an industrial scale. At presently, ca. 70 000 organic compounds are commercially available, with an annual global production of 100–200 million tons. Approximately one-third of all organic compounds produced end up in the environment, including water. Over 700 chemical compounds, including more than 600 organic compounds, many of which are biologically active, have been detected in drinking water samples.

Volatile organohalogen compounds and pesticides are particularly important pollutants among organic compounds as a result of their common use, persistence in the environment, and toxicity. They are primarily anthropogenic. Volatile organohalogen compounds are used mainly as solvents, cleaning and degreasing agents, blowing agents, polymerization modifiers, and heat-exchange fluids. As wastes, they find their way into lakes and rivers, and then into seas and oceans. Their concentrations in water and air are very variable and depend upon atmospheric conditions due to the washing by rain and evaporation from water during long periods of warm weather. It is estimated that the annual global production of organohalogen solvents alone amounts to several million tons.[3]

One of the most important sources of organohalogen compounds, particularly volatile ones, is water disinfection by chlorination.[1,3–10] The actual disinfecting agent is hypochlorous acid formed in the course of a disproportionation reaction taking place when chlorine dissolves in water. During chlorination, humic and fulvic compounds (so-called precursors), harmless and naturally occurring in water, are converted into organohalogen compounds which are dangerous to human life and health. The largest group of compounds formed during chlorination is the trihalomethane (THM) group. These are chloroform, the most abundant compound, bromodichloromethane, dibromochloromethane, and tribromomethane.[1,3–10] Organobromine compounds are formed when the water being chlorinated contains a large amount of bromides or when the chlorine used for disinfection is contaminated with bromine. Hypobromous acid formed in the reaction of bromide ions with hypochlorous acid reacts with an organic matrix about 200 times faster than does hypochlorous acid.[8] The amount and kind of organohalogen compounds formed depend upon the water pH, the amount of chlorine used and the content of organic matrix (total organic carbon (TOC)) in chlorinated water.[1,3–10]

THMs are not the only organohalogen compounds formed in the course of chlorination. Other volatile organochlorine compounds, such as tetrachloromethane, chloroethylene, 1,1-dichloroethylene, 1,1,2-trichloroethylene, tetrachloroethylene, 1,1,1-trichloroethane, and 1,2-dichloroethane, are also commonly found in chlorinated water. In addition, chlorination of humic substances and organic water pollutants yields a variety of other derivatives, of which over 100 have already been identified, including chlorinated acetone, chlorinated acetonitrile, chloropicrin, chloral, chloroacetic acids, chlorinated ethers, chlorophenols, and chlorinated ketones.[3–10] Koch and Krasner[10] estimated that among organohalogen compounds formed during the chlorination of water, 77% are THMs, 15% haloacetic acids, 3% halonitriles, 4% trichloroacetaldehyde hydrate and 1% the remaining compounds.

Pesticides are another group of organic compounds hazardous to human health and life.[1,11–13] They increase crop yields by reducing the amount of a crop that is lost to pests, and control diseases transmitted by insects. Pesticides are necessarily toxic, as they are used in agriculture, industry, and households to kill weeds (herbicides), insects (insecticides), fungi (fungicides), rodents (rodenticides), molluscs (molluscicides), mites (acaricides), roundworms (nematicides), aphids (aphicides), and eggs (ovicides). They are also used as

fumigants, attractants, and repellents.[1,11–13] The chemical structures of pesticides are very diversified, including organohalogen compounds, organophosphates, carbamates, triazines, and phenol derivatives.

2 CLASSIFICATION OF TECHNIQUES FOR THE ISOLATION AND DETERMINATION OF ORGANIC COMPOUNDS IN WATER

Anthropogenic organic compounds occur in water at relatively low concentration levels, but even at this level are dangerous to the life and health of humans and flora and fauna. This low concentration causes, in the majority of cases, the need for isolation and preconcentration of the analytes from the complex water matrix. Sample pretreatment, the initial stage of an analytical procedure, becomes the essential stage in environmental analysis. According to the participants in a survey,[14] among analytical laboratories the sample pretreatment takes up 61% of total time of analysis and is a source of 30% of the errors generated during sample analysis. The above data clearly indicate that sample pretreatment, including isolation and preconcentration of the analytes, is an essential step in trace analysis. The methods of isolation and preconcentration of organic compounds from water are closely associated with the kind of analytes, their volatility, polarity, stability, water solubility, solubility in organic solvents, etc. Many techniques for the isolation and preconcentration of the analytes from water have been developed.[4,5,11,15–23] The most popular are solvent or liquid–liquid extraction (LLE), SPE, solid-phase microextraction (SPME) and techniques utilizing the distribution of solute among the liquid and the gaseous phase (headspace (HS), purging). Less commonly used methods are supercritical fluid extraction (SFE), freezing out, lyophilization, vacuum distillation, steam distillation, and membrane processes (reverse osmosis, ultrafiltration, dialysis).[4,5,11,15–23] For final determination, GC with specific detection methods such as ECD, nitrogen–phosphorus detection (NPD) flame photometric detection (FPD), atomic emission detection (AED) and electrolytic conductivity detection (ELCD) or universal methods, such as flame ionization detection (FID) or mass spectrometry (MS) are used. Liquid chromatographic methods with detection methods such as ultraviolet (UV) detection, diode-array detection (DAD), electrochemical detection or fluorescence detection are also often used. The characteristics of typical detectors used in GC are listed in Table 1. A schematic diagram of utilization of various isolation techniques for the determination of organic compounds in water is shown in Figure 1.[17] In Figure 1 are shown two main ways for the determination of organic compounds in water: individual compound or total parameter determination. Total parameters such as TOC, dissolved organic carbon (DOC) and suspended organic carbon (SOC) are used to characterize the content of organic compounds in water. Other parameters are defined in terms of the method of isolation of an organic fraction from water: VOC or purgeable organic carbon (POC), EOC and AOC. However, total parameters measuring the carbon content in an organic fraction are not particularly suitable as an estimate of anthropogenic water pollutants and their hazard to human health, since a decisive majority of organic compounds in water are biogenic.

Two main methods for the isolation and preconcentration of organic contaminants from water are LLE and SPE but, although simple and not requiring sophisticated apparatus, they have a number of drawbacks. More volatile compounds can be evaporated during these operations (e.g. THMs, other volatile halocarbons, volatile hydrocarbons) with a consequent decrease in recovery and low results being obtained. Some compounds are poorly

Table 1 Characteristics of typical detection methods used in GC

Detection method	Type	Classification	Applicability	Detection limit (pg)	Linear dynamic range
FID		Universal	Hydrocarbons	100	10^6
ECD	Cl_2, Br	Selective	Haloorganic compounds	5	10^4
	Polyfluoride			0.05	
TCD, NPD	Nitrogen	Selective	Nitrogen and phosphorus	0.2	10^5
	Phosphorus		organic compounds	0.1	10^4
FPD	Phosphorus	Specific	Phosphorus and sulfur organic	0.5	5×10^4

extracted from the water phase (e.g. ketones, alcohols) or the partition coefficient is strongly dependent on the matrix (unknown). The LLE method requires the use of large volumes of expensive, and possibly toxic, solvents. After SPE (except methods using thermal desorption for volatile compounds), solvents are also used, although not in such large quantities. The solvents are subsequently evaporated and after analysis create a problem of storage of hazardous waste. Working with these solvents may require the use of personal protection devices, such as respirators. The formation of emulsions is yet another problem with LLE. The solvents and sorbents used for extraction should be of very high purity, free from traces of the analytes and other potential interferents. Otherwise, a large background is obtained, precluding the determination.

HS techniques[4,11,15–17] are limited to volatile compounds and the partition coefficient is also strongly dependent on the matrix (unknown) and affects the accuracy. Additionally, some compounds, belonging to priority pollutants, are not purgeable from the water phase (e.g. acrylonitrile, propionitrile).

The only method for the determination of organic compounds in water which avoids the isolation and preconcentration step uses direct injection of an aqueous sample on to a GC column.

3 DETERMINATION OF ORGANIC COMPOUNDS BY DIRECT AQUEOUS INJECTION

DAI[4,16,24–81] is the simplest method for avoiding the often very complicated steps of isolation and preconcentration of analytes. For analysts the best idea is to introduce the sample directly to the GC column without any pretreatment. This technique also avoids all problems related to the hot vaporizing injection technique by introduction of the sample directly into the oven-thermostated column inlet. However, the aqueous samples, particularly environmental, have a very complex nature of the matrix and a large content of inorganic salts and organic compounds (humic acids, other contaminants). These compounds can rest on the top of column and cause additional retention or deactivation of the column. Some low-volatility compounds can be eluted from the column during a long period of time. After direct introduction of aqueous samples, during evaporation, a

large volume of water vapor is formed. At 20 °C from 1 μL of water, 60 mL of carrier gas saturated with water vapor is produced. A large volume of water can deactivate the stationary phase and the layer and change the chromatographic condition of the column. Another problem is retention of water on the chromatographic column. This is, particularly in a packed column, a tedious and time-consuming process. Water also has a high surface tension (poor wetting properties) and poor properties concerning solvent effects.

Most of the detectors used in chromatographic determinations are not compatible with water. This concerns, especially, flame-based detectors or infrared (IR) or other spectroscopic detectors. The flame in an FID or thermionic NPD instrument can be blown out by water. On the other hand, in the case of an IR detector the measurement cell, often made from KBr, can be diluted in water. Relatively resistant to the presence of water are ECD and ion trap detection (ITD) instruments.

3.1 Determination of Organic Compounds by Direct Aqueous Injection into Packed Columns

The idea of DAI on to a chromatographic column is very old and for liquid and ion chromatography has been widely applied since the beginning of these techniques, but here water is used as one of the components of the mobile phase. A reversed-phase PRP-1 column, sodium form of Aminex A-5, and a Waters Pak cation-exchange column with a Dionex normal cation suppressor have been used. The application of this technique for GC is more difficult. In the beginning of the application of this technique in GC, packed columns were used.

One of the most popular column packings in the early days was graphitized carbon black (GCB). This sorbent was used by Di Corcia et al.[24,25] for determination of aliphatic amines (C_1–C_{16}) in aqueous solution. The application of GC for the determination of strong organic bases, such as amines, was always a difficult analytical problem, because of strong solid–gas interactions, the loss of sample, ghosting phenomena and badly tailed elution. It was very important to prepare the sorbent for packing of the column in a very special way. They had used modifications of Sterling FT-G (Carbopack A) and Vulcan GCB (Carbopack B) deactivated with suitable amounts of KOH and covered with polyethylene glycol (PEG), e.g. PEG-20M or PEG-1500. The GC apparatus used (Carlo Erba Model GI) equipped with FID allowed one to inject an aqueous sample (1.5 μL) directly into the column packing. Water was eluted after analytes. It was found[25] that the use of Carbopack B (60–80 mesh), modified with 0.3% potassium hydroxide and 4.8% PEG 20M, gave the best results with regard to the following: reducing the instability of the selectivity and the retention times of amines on prolonged use of the column, the intolerance of the packing to injections of water, baseline disturbances, and interferences caused by alcohols and peak tailing. The detection limit for this method was about 1 mg L^{-1}.

FID does not produce sufficient information for the identification of analyte compounds among the variety of different compounds that could be present in a water sample. Computerized gas chromatography/mass spectrometry (GC/MS) overcomes this difficulty. In 1974, Harris et al.[26] described a method for the direct analysis of water samples by GC/MS. A 1–10 μL sample of water sample was injected on-column into a Varian Model 1400 GC interfaced with a Finnigan Model 1015 C quadruple mass spectrometer. The different types of packed column used were as follows:

1. stainless-steel tube packed with Gas Chrom Q (60–80 mesh) coated with 5% Carbowax 20M;
2. coiled glass column (2 mm i.d.) packed with acid-washed Chromosorb W (60–80 mesh) coated with 10% free fatty acid phase (FFAP);
3. coiled glass column (2 mm i.d.) packed with Chromosorb 101 (50–60 mesh).

From the column with Gas Chrom Q (1), water was eluted much later than the analytes and so the ion source potential and multiplier were applied immediately after injection and switched off during elution of water. From the column with Chromosorb 101 (3), water was eluted very quickly, so the source and multiplier were not applied and data acquisition was not begun until the water had eluted.

This method can be applied to amines, ketones, alcohols, and aliphatic hydrocarbons, but only for domestic sewage and waste effluent water samples owing to very high detection limits (1–50 mg L^{-1}), depending on a variety of factors.

A much better concentration range (from 0.1 to 50 μg L^{-1}) was achieved by Fujii,[27] who introduced much larger samples (up to 100 μL). His method, also based on DAI and GC/MS analysis, was dedicated to haloorganic compounds present in tap water. Two columns were used: the precolumn contained Chromosorb W NAW (60–80 mesh) coated with 10% diglycerol and the main column packed with Chromosorb W AW DMCS (60–80 mesh) coated with 5% SE-30. The elution time of the overload water peak with the diglycerol precolumn was very long and all organohalogen compounds were eluted much earlier. This method can be applied to all compounds which elute before water, e.g. phenols, alcohols, ketones, hydrocarbons, and amines. The longer diglycerol precolumn should be selected in order to elute the higher boiling compounds before the water.

The analytes should not be eluted on the tail of the overload water peak. The main column makes it possible to achieve the required separation. The column temperature was maintained at 100 °C isothermally. On the outlet of the main column a three-way valve was positioned to prevent water (eluting after analytes) from entering the MS detector (possibility of damage to the filament or electron multiplier). High sensitivity and precision were achieved by operation in the mass fragmentography mode. Identification was supported not only by known retention times but also from the selectivity afforded by SIM. Detection limits depended upon the kind of compounds and varied from 0.1 μg L^{-1} for trichloromethane, dibromomethane, and dichloroethene to 0.8 μg L^{-1} for tetrachloromethane. The time of analysis for organohalogen compounds was about 6.5 min, but after analysis the column had to be maintained at 100 °C for at least 50 min to remove water and other less volatile compounds before the next analysis.

For the determination of haloorganic compounds, highly specific selective detection methods, such as ECD or ELCD (Hall detector) are more suitable. Nicholson et al.[28] described a method for the determination of haloforms in drinking water using DAI into a GC column (Varian 2400 GC equipped with ECD) packed with Chromosorb 101 (60–80 mesh). Also very interesting is the comparison of the DAI/GC/ECD method with the gas purging GC/ELCD method. Excellent agreement between the two methods was demonstrated. The gas purging method is very popular for the determination of volatile compounds in water but needs additional equipment.

In the DAI/GC/ECD method, 9 μL of aqueous sample volume was injected into the column operated under isothermal conditions (either 130 or 150 °C) and a 20-min analysis time was used. The column oven must be operated isothermally to prevent excessive baseline drift. The temperature depended on the range of compounds analyzed. This technique when automated and working with an autosampler allows analyses of up to 60 samples per day. The detection limit for this method for chloroform, bromodichloromethane, chlorodibromomethane, and carbon tetrachloride was at or below 1 μg L^{-1}. The authors observed that the results obtained by DAI/GC/ECD can be treated as the maximum haloform concentration which can be reached while the water is in the distribution system, because of reactions of the precursors and the other haloforms at high injector temperatures. The difference was attributed to nonpurgeable chlorinated compounds, formed as a result of the chlorination process, that supposedly decomposed in the heated injection port of the gas chromatograph to yield chloroform.

Similar investigations concerning the determination of THMs were also conducted by Pfaender et al.[29] For analysis by DAI they used a Perkin-Elmer Model 900 gas chromatograph equipped with two stainless-steel columns (column for analysis and column for makeup) packed with 50–80 mesh Porapak Q operating at 150 °C and with ECD. The novelty introduced by them in the construction of the apparatus (except the column for makeup) was a four-way valve installed in the manifold between the column outlet and the detector inlet. The valve permitted the effluent from the analytical column to be vented while the water peak was emerging and then redirected to the detector. During venting, the effluent from the makeup column was connected to the detector. It had been observed that injection of 1 μL of water into the electron capture detector caused no appreciable changes in its performance, but injection of larger quantities of water caused a decrease in detector sensitivity. Installation of the valve permitted a larger volume of water to be injected without a decrease in detector sensitivity. This made it possible to inject on to the column 20 μL of the sample and the detection limit reached for chloroform was 0.5 μg L^{-1}.

Another possibility for removing water during the determination of haloforms in water after DAI was described by Simonds and Kerns,[30] water being selectively removed by diffusion across a permselective membrane prior to the sample entering the chromatographic column. Nafion® (a perfluorosulfonic acid polymeric material made by DuPont) with strong adsorption properties for water, was used as a membrane. A volume of 1–20 μL of water was injected into a separate heated (150–200 °C) injection port, vaporized and the water vapor permeated through the walls of Nafion® tubing, positioned ahead of the chromatographic column, to a stream of dry nitrogen gas sweeping the outer surface of tubing. Any traces of organic compounds were directed to the chromatographic column and were chromatographed. Hydrocarbons, most aldehydes, esters, and ethers are not removed by the Nafion® tube, whereas highly polar compounds such as alcohols, amines, and certain ketones are partially or wholly removed with the water. Since water is removed before the sample enters the chromatographic column, any appropriate column can be used. Two separate types of apparatus were used during investigations. The first used during preliminary experiments was a Pye 104 (Pye Instruments) gas chromatograph equipped with aluminum tubing maintained isothermally at 60 °C and packed with Carbowax 400/Porasil C, Low K (Waters) and an electron capture detector (^{63}Ni ECD). The second apparatus used was a Varian 2100 gas chromatograph equipped with a glass column maintained isothermally at 75 °C and packed with 3% Carbowax 20M coated on Carbopack B (60–80 mesh) and an electron capture detector (^{3}H-Sc ECD). The

detection limits for haloorganic compounds varied from 0.05 $\mu g\,L^{-1}$ for carbon tetrachloride, 0.1 $\mu g\,L^{-1}$ for trichloroethylene and 1,1,1-trichloroethane, 0.3 $\mu g\,L^{-1}$ for chloroform, 35.0 $\mu g\,L^{-1}$ for 1,2-dichlorobenzene and 1,3-dichlorobenzene to 100.0 $\mu g\,L^{-1}$ for dichloromethane and 1500 $\mu g\,L^{-1}$ for chlorobenzene.

A comparison of the DAI method with a simple direct HS technique was also investigated. Both methods gave similar results.

Loung et al.[31] used DAI techniques to investigate drinking water in London. Water samples were collected in a glass vial equipped with a Mininert valve set into a screw cap which allowed the introduction of 5 µL of water sample by a syringe directly into the chromatographic column. This analysis was carried out using a Hewlett-Packard 5713 A gas chromatograph equipped with a glass column packed with Chromosorb 101 (100–120 mesh) operated isothermally at 150 °C and an electron capture detector. Detection limits for THMs under these conditions were about 1 $\mu g\,L^{-1}$.

Hou and Tang[32] used a special column for the rapid elution of water during determination of halocarbons in drinking water. Volumes of 0.4–1 µL of water sample were introduced directly on to the GC column (Hewlett-Packard 5890) packed with GDX-103 (a Chinese sorbent similar to Porapak) coated with 1% of SE-30. The final determinations were carried out with an electron capture detector (^{63}Ni ECD). The detection limits varied from 0.4 $\mu g\,L^{-1}$ for tetrachloromethane, ~1 $\mu g\,L^{-1}$ for chloroform, bromochloromethane and dibromochloromethane to 2.6 $\mu g\,L^{-1}$ for tribromomethane.

DAI was proposed also in the United States Environmental Protection Agency (USEPA) standard method (Method 8010),[33] but only in very limited applications (e.g. aqueous process wastes). In this method first of all the purge-and-trap (P&T) technique had been used for the determination of 39 volatile haloorganic compounds in water. The detection limit for the P&T method varied from 0.02 $\mu g\,L^{-1}$ for 1,1,2-trichloroethane through 0.05 $\mu g\,L^{-1}$ for chloroform up to 0.52 $\mu g\,L^{-1}$ for chloroethane, whereas for DAI it was very approximately 10^4 $\mu g\,L^{-1}$. There are two columns which can be used in this method, a stainless-steel column packed with Carbopack-B (60–80 mesh) coated with 1% SP-1000 or a stainless-steel column packed with chemically bonded *n*-octane on Porasil-C (100–120 mesh). Detection was achieved with a halogen-specific detector.

DAI has also been applied to the determination of other compounds. Fussell and McCalley[34] described a method for the determination of volatile fatty acids (C_2–C_5) and lactic acid in aqueous samples of silage based on direct injection of samples (1–2 µL) on to a glass GC column (Pye Unicam) which was packed with GCB coated with Carbowax 20M. This packing gave improved results compared with porous polymer column materials (Porapak Q, Porapak QS, Chromosorb 101). The final determination was carried out using FID. This method was more selective, more precise, and less time-consuming than a classical distillation procedure. The method gave an excellent linear calibration response for volatile fatty acids from 0 to 500 mg L^{-1} and for lactic acids from 250 to 10 000 mg L^{-1}. The detection limit varied from 2 mg L^{-1} for fatty acids to 60 mg L^{-1} for lactic acid. To protect the column, the quartz-wool insert positioned on the top of the column should be renewed regularly if the samples contain non-volatile compounds. Also, the first few centimeters of packing can be replaced.

Malaiyandi and Goddard[35] used DAI for the determination of amines in steam and boiling industrial waters. The addition of amines to boiling industrial water prevents the corrosion caused by CO_2. However, amines are strongly irritant to the skin, mucous membranes, and respiratory tract, so it is necessary to control their content. Amines are highly hydrophilic, so it is very difficult to isolate them from the aqueous sample without loss of analytes. Additionally, the partition coefficient for amines during LLE is not favorable, so DAI is the best approach for the determination of amines in water. The method was employed for the determination of morpholine, cyclohexylamine, and diethylaminoethanol. Amine analysis under the usual GC conditions suffers from several drawbacks: adsorption or even decomposition in the column, bad tailing and ghosting. In the described method, from 2 to 5 µL of aqueous sample were injected directly on to the GC column packed with GCB (60–80 mesh) coated with 4.8% PEG 20M and 0.4% potassium hydroxide. Temperature programming of the column and FID for final determination were used. To prolong the life of the column packing, a guard insert was placed before the column. This guard insert containing a wad of silanized and ammonia solution-treated glass wool could be removed and reused after cleaning. It protected the column from the accumulation of alkali metal carbonates and hydrogen-carbonates and nonvolatile organic compounds on the top of the column, which can plug the column. The detection limits for morpholine, cyclohexylamine, and diethylaminoethanol varied from 52 to 55 ng for one injection.

3.2 Determination of Organic Compounds by Direct Aqueous Injection into a Capillary Column

3.2.1 Capillary Columns in Gas Chromatography

The real issue for the development of GC and the application of DAI is connected with introducing to practical use a capillary column with a polar or non-polar stationary thin-liquid film or thin layer. Different

groups of researchers have dealt with these problems and their applications. The initial work connected with the application of a capillary column for GC was performed by Desty,[36] Schomburg et al.[37,38] Novotny et al.[39,40] and van Rijswick and Tesařik.[41] This method was improved and developed by Grob et al.[42–49]

Initially there were many problems with the preparation of columns, specifically with their repeatability and reproducibility, thermal stability, and fragility. For a long time capillary columns were not widely used. However, capillary columns have many advantages.[37–49] Compared with packed columns they have a much higher separation efficiency in terms of effective plate numbers per meter and the total effective plate numbers that can be achieved in long columns. Also, tailing is much lower. It is now possible without any problems to prepare or to buy capillary columns which can provide high separation efficiency, defined polarity, and temperature stability. Low-volatility compounds can be eluted without decomposition at low temperatures with moderate retention times, because only small amounts of stationary liquids are contained in long columns. Capillary columns also have very low pressure drops, so long columns and high carrier gas flow-rates can be used.

In the studies by Novotny et al.[39,40] and Rijswick and Tesařik,[41] special attention was focused on the role of selective surface monolayers in wettability, the deactivation procedure, and the deposition of stationary phases on the capillary column, which are the most important parameters for column efficiency.

Schomburg et al.[37,38] made and etched a glass capillary column with dry hydrogen chloride and coated the etched surface with a stationary liquid phase (OV-101, LAC-3R-728, Carbowax 20M). The tailing of polar compounds can be reduced by coating the surfaces with a thin film of deactivating agent. Carbowaxes were found to be the best for this purpose. For the determination of aqueous samples, two procedures were used and double-column chromatography was proposed. The capillary columns must be protected against a large volume of water (highly polar solvent), which can change the separation efficiency by destroying the thin-film properties. Water can be trapped in the first column (precolumn) packed with a strongly polar stationary phase, such as Carbowax, and less polar analytes eluted before the water can be chromatographed on the main capillary column. After analysis, water can be back-flushed from the precolumn. The second procedure is to elute water, without passing through the main capillary column before the analytes, using a nonpolar Porapak precolumn, which traps analytes in the very first part. After elution of water, analytes can be back-flushed from the precolumn and with or without trapping (in the mantling tube made of stainless-steel and cooled or heated with a stream of nitrogen) directed to the main capillary column. There are two separate injection ports for each method. In this way, only small, negligible amounts of water are introduced to the capillary column. The other solution is to use two capillary columns,[14] the first as the trap and the second for the main separation.

3.2.2 Injection On-column in Gas Chromatography

The next, very important step was to introduce direct injection on-column. Conventional injection had been carried out via an evaporation step: split or splitless injection, the falling needle, or a precolumn. During evaporation, the sample is diluted in carrier gas, causing band broadening and a degradation of the detection limits. All vaporizing injectors possess various dead volumes from which the last traces of water vapor are eluted with a delay. Analytes can be absorbed in the injector, or the high temperature during evaporation can destroy some compounds, causing problems with quantitative determinations. Another problem is connected with the septum used on the top of the injection port. The septum can absorb analytes or emit some volatile components, causing tailing, artifacts, ghost peaks, and baseline drift. The syringe needle can introduce to the injector some trace of organic contaminants and in cutting the material of the septum it can add contaminants of rubber or plastic. The latter can plug the injector or the top of the column. This effect is especially dangerous for a capillary column. On-column injection eliminates many of these problems.

3.2.3 Injection On-capillary Column in Gas Chromatography

As far as we know, the first application of direct injection on a large-bore steel capillary column (0.03–0.06 mm i.d.) was described by Zlatkis and Walker.[50] The volume of sample introduced was up to 0.3 μL and the efficiency deteriorated rapidly for larger samples. In the next paper, written by Desty,[36] the introduction of the sample as a layer a few tenths of a micrometer thick on a few millimeters of wire of small enough diameter to enter the capillary column was proposed. Analytes were dissolved in the stationary phase on the top of the column at low temperature without decomposing it.

Application of on-capillary column injection for aqueous samples was realized by Grob et al.[42–49] Their work was fundamental for the development of the DAI technique. There were many problems to resolve for on-column injection: temperature, pressure, and flow conditions of the injector, kind of syringes used, design and functioning of the on-column injector, and the type of capillary columns and detectors. A syringe is the simplest and safest way to introduce a sample into a capillary column. The volume of sample introduced is well defined,

all the sample volume is introduced to the column and the syringe is easily cleaned. The outer diameter of the syringe needle should be at least 0.05 mm less than the inner diameter of the column. The needle, introduced into the column over a length of several centimeters, should not plug the column and the flow conditions of carrier gas. Some problems are caused by partial sample vaporization out of the hot syringe needle and the difficulty with stabilization of the pressure of the carrier gas at the column inlet during injection, because we have to work without a septum. The sample starts to evaporate at the injection point after deposition on the column wall (after leaving the outlet of the needle in the capillary column), not in the syringe needle (including its tip), so the injector has to be cooled. The injection point has to be sufficiently far from the oven wall inside the oven to reach the controlled oven temperature, but not so far as to prevent evaporation of the sample in the needle. It depends upon the design of the oven, but a 10-mm average distance from the wall of oven to the end of the needle is advised by Grob and Grob.[42] The temperature of injection should be such as to prevent explosive evaporation with a sudden pressure increase, which can flush back part of the sample into the cool injector. The vapor pressure of the water should be below the carrier gas inlet pressure. On-column injection produces a much lower relative standard deviation for all analytes than the conventional injection procedure and no breakdown products were observed.

3.2.4 *Determination of Haloforms in Water Using Direct Aqueous Injection on to Capillary Columns*

The determination of haloforms in water using DAI on to a capillary column and ECD was the most spectacular application proposed by Grob et al.[43–49] An apolar, extremely inert column was applied to elute water before the volatile haloorganic compounds. Water should be eluted even before much more volatile compounds such as methylene chloride, but there is a need for strong retention of the apolar halocarbons without broadening of the water peak. Non-volatile compounds and inorganic salts are left in the inlet of column. Water is eluted for a longer time during the analysis of natural samples containing inorganic salts than for model samples prepared from deionized water (the dry inorganic salts retain traces of water). The inlet of the column can be periodically broken off or the precolumn consisting of an empty, 1–1.5-m long fused, deactivated (usually silylated) but uncoated silica capillary column should be applied. The precolumn, which retains nonvolatile compounds, should after some period be shortened or replaced. A capillary column coated with an extremely thick film (about 5 μm) of methylsilicone phase (SE-30) or a slightly more polar, phenyl-containing phase (SE-54) was applied. This film was more suitable than the thick films commonly used (1–2 μm). This thick film causes even very volatile organic compounds to have a relatively long retention time, but it also causes a decrease in column efficiency. For the analysis of high-boiling organic compounds a thinner film of nonpolar stationary phase is recommended.

The column length depends on the compounds to be analyzed, but longer columns result in a decrease in sensitivity. An increase in retention time for halocarbons can be achieved by increasing the column length or the film thickness. Volumes of 0.5–2.0 μL of the aqueous samples were injected on to a capillary column (Carlo Erba Model 4 160 gas chromatograph) operating isothermally (103–104 °C) and connected to an electron capture detector (Carlo Erba ^{63}Ni ECD) heated to 350 °C. Cooler columns can accumulate some residual water, causing baseline drift and poorer resolution of high-volatility halocarbons. At higher column temperatures, water vapor can damage the column and cause peak splitting. The optimal length of the column was established as 25–30 m. On-column injection produced much sharper halocarbon peaks than splitless injection. During on-column injection, analytes are evaporated from the water inside the column, whereas during splitless injection analytes are diluted with the carrier gas in the injector, forming a broad initial band and causing peak broadening and even distortion. The detection limits obtained varied from 0.025 μg L^{-1} for tetrachloroethylene, through 0.03 μg L^{-1} for chloroform, up to 0.6 μg L^{-1} for trichloroethane. For the analysis of heavier halocarbons (e.g. chlorobenzenes), a capillary column coated with a thicker film (0.8 μm) is recommended.

3.2.5 *Commercially Available Methods for the Determination of Haloforms in Water Using Direct Aqueous Injection on to Capillary Columns*

Application sheets for the determination of halocarbons in drinking water using DAI on to a capillary column are available for Carlo Erba and Hewlett-Packard gas chromatographs equipped with ECD.[51–53] These are elaborations on the basic work of Grob et al.[42–49]

In the case of the Carlo Erba application sheet,[53] cold on-column injection with secondary cooling, a fused-silica capillary column (FSCC) (30 m × 0.32 mm i.d.) PS 255 (coated with a 5-μm film) and a gas chromatograph [Carlo Erba 4160 high-resolution gas chromatography (HRGC) system] equipped with an electron capture detector (ECD 40/400) were used. The injection volume of the water sample was 2 μL. The column was operated isothermally at 104 °C. The injection temperature was higher than the boiling point of water, so cold-on-column injection with secondary cooling was necessary to prevent sample back-flushing.

To prevent contamination of the analytical column by nonvolatile organic and inorganic compounds, an easily replaceable, uncoated and deactivated precolumn placed before the analytical column was used as a retention gap. The precolumn was connected with the analytical column by a zero dead volume butt connector. The other recommended chromatographic conditions are: detector ECD, operated at 350 °C in the constant-current mode; makeup gas, nitrogen (50 mL min^{-1}); carrier gas, hydrogen (2 mL min^{-1}). The use of an autosampler (AS 550) for routine application was also advised. The dynamic filling method (using pressurized inert gas) utilized by the automatic sampler avoids gas bubble formation in the syringe, which is responsible for the loss of volatiles and irreproducible injection. Detection limits for chosen compounds were as follows: 0.6 μg L^{-1} for methylene chloride, 0.03 μg L^{-1} for 1,1,1-trichloroethane, 0.02 μg L^{-1} for chloroform, 0.015 μg L^{-1} for tetrachloromethane, 0.03 μg L^{-1} for trichloroethylene, and 0.025 μg L^{-1} for tetrachloroethylene.

Temmerman et al.[51] described a similar method, but with some changes of the chromatographic conditions. They also used a cold on-column injector with secondary cooling and a Carlo Erba 5300 HRGC gas chromatograph equipped with ECD operating at 350 °C. In this method, 1 μL of water sample was injected on-column and used a 1.5 m × 0.53 mm i.d. uncoated and undeactivated FSCC as a retention gap. This was connected by a press-fit connector to a 30 m × 0.53 mm i.d. FSCC coated with a 5-μm film of methylsilicone (DB-1) operating isothermally at 104 °C. The undeactivated retention gap slightly improved the elution of the water peak. As the carrier gas, helium at a flow-rate of 1–2 mL min^{-1} was used, and, as the makeup gas, Ar–CH_4 at a flow-rate of 60 mL min^{-1} was used. In comparison with solvent extraction (with pentane), the DAI method gave better recoveries.

Temmerman et al. elaborated on the basic work of Hewlett-Packard Application Note 228-135[52,54,55] which was applied as USEPA Method 502.1–3.[55] This method used cool on-column injection, an HP 7673A automatic sampler, an HP 5890 Series II gas chromatograph equipped with a retention gap (1.5 m × 0.53 mm i.d. uncoated, undeactivated FSCC), a 30 m × 0.53 mm i.d. capillary column coated with a 2.65-μm film of HP-1 and an electron capture detector heated at 300 °C. The other chromatographic conditions were as follows: injection of 1 μL of water sample at 50 °C; oven temperature program, 50–150 °C at 10 °C min^{-1}; detector make-up gas, Ar–CH_4 at a flow-rate of 60 mL min^{-1}; carrier gas, hydrogen at an inlet pressure of 10 kPa. The detection limit was 1 μg L^{-1} for chloroform and 0.5 μg L^{-1} for other THMs. The linearity for THM determination was very good up to a concentration of 500 μg L^{-1}.

Hewlett-Packard later introduced some changes.[54] They noticed that the retention gap should have a polar or medium-polarity surface and so should be deactivated with PEG or with a medium-polarity reagent, not with dimethylsilicones or an apolar silylating reagent. The result was that they recommended as the retention gap a 5 m × 0.53 mm i.d. deactivated capillary column, and as the analytical column a 30 m × 0.53 mm i.d. capillary column covered with a 1-μm film of HP-1.

A similar solution for the determination of THMs by DAI using ECD was elaborated by Carmichael and Holmes[56] for Varian Instrument Business Manufacturing Facilities.[57,58] A septum-equipped programmable detector (special construction) with an on-column glass insert was used for cold on-column injection (without secondary cooling), an uncoated deactivated fused-silica column (4 m × 0.53 mm i.d.) as the retention gap and a 0.53 to 0.32 mm press-fit connector, an analytical column (30 m × 0.32 mm i.d.) coated with a film of DB-624 cyanopropyl stationary phase (1.8 μm) and a sheath foil electron capture detector (^{63}Ni ECD) were used to determine THMs. After injection of 1–5 μL of the sample (the injector was held at 60 °C for 0.04 min and then heated to 150 °C at 75 °C min^{-1}), the column was held for 3 min at 104 °C and then heated to 150 °C at 10 °C min^{-1}. The carrier gas used was helium (0.2 m s^{-1} or 10 psi head pressure) and the makeup gas used was nitrogen (50 mL min^{-1} for a Varian 3400 and 25 mL min^{-1} for a Varian 3500 GC). The DB-624 analytical column gives effective resolution of haloforms and has a low retention of water and hypochloric acid. The retention gap should be replaced after a few analyses or solvent-washed. The detection limit was lowered to 0.043 μg L^{-1} for chloroform, 0.016 μg L^{-1} for bromodichloromethane, 0.017 μg L^{-1} for dibromochloromethane and 0.060 μg L^{-1} for bromoform when a smaller cell volume in ECD was applied. This method was introduced on to the market with success and is used in many laboratories.[56–59]

3.2.6 Determination of Other Organic Compounds in Water Using Direct Aqueous Injection on to Capillary Columns

DAI on to a capillary column was successfully introduced for the determination of volatile organohalogen compounds in water. The success was due to the very high sensitivity of the electron capture detector routinely used in this method. With other compounds, which are not so volatile and do not contain halogen, it is more difficult. Ellington and Trusty[60] described such a method for the determination of trimethyl and triethyl phosphates in water. The widespread use of these compounds as plasticizers, pesticides, and flame retardants causes

their release into the environment. These compounds are very soluble in water, so their isolation using LLE or SPE is very difficult. They used a Hewlett-Packard 5890 gas chromatograph equipped with an automated cool on-column aqueous injector, with a retention gap of 1–1.5 m × 0.53 mm i.d. uncoated, deactivated FSCC. The analytical column used was a 15 m × 0.53 mm i.d. DB-5 column coated with a 1.0-μm film or a 13 m × 0.55 mm i.d. DB-Wax column coated with a 1.0-μm film. FID at 250 °C was used. The column temperature was held initially at 90 °C for 1 min, then programmed to 115 °C at 5 °C min^{-1} and to 160 °C at 70 °C min^{-1} and held at 160 °C for 2 min. The carrier gas used was helium at a flow-rate of 10–12 mL min^{-1}, and nitrogen acted as the makeup gas at a flow-rate of 25 mL min^{-1}. The flow-rates of hydrogen and air were 32 and 330 mL min^{-1}, respectively. The injection volume was 1 μL. The samples were buffered at pH 3 for phthalate and pH 7 or 11 for phosphate. The main problem encountered is the buildup of the buffer salts which necessitates rinsing of the column or periodic replacement of the retention gap. Good linearity and precision in determination were obtained.

A method for the determination of volatile fatty acids using on-column injection of an aqueous solution was described by McCalley.[61] A Hewlett-Packard 5890 gas chromatograph was used with on-column injection (0.5 μL of analyte water or aqueous solution of oxalic acid, 0.03 mol L^{-1}). The analytical column was either a 10 m × 0.53 mm i.d. fused-silica column containing cross-linked FFAP, film thickness 1.0 μm, or a 15 m × 0.55 mm i.d. DB-Wax column coated with a 1.0 μm film. A single flame ionization detector operating at 200 °C was used. An electronically stored blank chromatogram was used to eliminate the effect of stationary phase bleeding during the temperature program. The carrier gas was helium at a flow-rate of 31 cm s^{-1}.

DAI with GC coupled to Fourier transform infrared (FTIR) spectroscopy was used by Payne and Collette[62] for identification of bis(2-chloroethyl) ether hydrolysis products: 2-(2-chloroethoxy)ethanol (2CEE), diethylene glycol (DEG), *p*-dioxane (*p*DOX), 2-chloroethanol (CE) and ethylene glycol (EG). They also used a Hewlett-Packard 5890 gas chromatograph equipped with a cool on-column injection system, comprising a 30 m DB-Wax (a PEG phase), 1.0-μm Megabore™ column and FTIR with a Digilab FTS-60 spectrometer. This was equipped with a mercury–cadmium–telluride detector using a light pipe-based interface operated at 220 °C. The FTIR detector was connected in series with a thermal conductivity detection (TCD) instrument. The column temperature was programmed from 80 to 220 °C at 15 °C min^{-1} and held at 220 °C for 10 min. Helium was used as the carrier gas. Between the column outlet and FTIR interface, a Valco six-port valve was installed. During water elution from the column (before the analytes on this column), the outlet of the column was connected to a TCD instrument and, during elution of analytes, to the FTIR interface. The injection volume was 1 μL.

Gurka et al.[63] applied DAI coupled with GC/FTIR or GC/ion trap spectrometry (ITS) for the determination of a wide range (13) of organic compounds, which were water soluble, low-molecular-weight, and poorly or not purgeable efficiently from water. These included alcohols, ketones, nitriles, and esters. They used for this purpose a Hewlett-Packard Model 5965 A IR detector (containing a narrow-band mercury–cadmium–telluride detector) and a Finnigan Model ITS 40 (equipped with a septum programmable injector (SPI) and scanned from 29 to 300 u). Both detectors were interfaced to a gas chromatograph equipped with an on-column injector. In the case of GC/FTIR analysis, a Hewlett-Packard Model 5890 gas chromatograph equipped with a fused-silica capillary column (FSCC) (27.5 m × 0.32 mm i.d.), coated with a 10-μm Pora Plot Q film, was used. After 5 min at 60 °C, the GC column was heated to 200 °C at 10 °C min^{-1} and held at 200 °C for 8 min. The light pipe and transfer lines were also heated to 220 °C. As the carrier gas, helium was used at a flow-rate of 33 cm s^{-1}. No makeup gas was used. Helium was dried by passing it through a cartridge drier. The detection limits varied from 5 to 100 mg L^{-1} so this method is not useful for routine analysis of drinking water, but can be used for industrial process streams and effluents.

In the case of GC/ITS analysis, the Varian Model 3400 gas chromatograph equipped with an FSCC (1.5 m × 0.32 mm i.d.) coated with a 0.5-μm polysiloxane film with 5% phenyl groups (PTE-5) and a 30 cm × 0.05 mm i.d. fused-silica restrictor connected between the analytical column and the SPI to limit the flow of carrier gas to the ITS 40 manifold (it should be less than 1.5 mL min^{-1}) was used. After 1 min at 60 °C, the GC column was heated to 240 °C at 16 °C min^{-1}. As the carrier gas, helium at a flow-rate of 45 cm s^{-1} was used. The injection volume was 2 μL. The detection limits varied from 4 to 200 μg L^{-1}.

The GC/ITS method was improved by Pyle and Gurka[64] for the determination of 27 volatile organic compounds. They had noticed that injections greater than 0.2 μL provided imprecise results caused by residual water eluted together with the analytes, so 0.2 μL was routinely injected on-column. Using similar equipment to before[63] with a Restec column (30 m × 0.53 mm i.d. XTI-5 Megabore™ FSCC coated with a 1.5-μm film of bonded 5% phenyl and 95% dimethyl polysiloxane liquid phase), they changed the working conditions of the detector, specifying the rf voltage of the ion trap to exclude water ions from the manifold. Single-ion and triple-ion quantitation methods were tested. Better precision

and detection limits (about twofold) for the triple-ion method were obtained. The detection limits varied from 1.56 μg L^{-1} for ethylbenzene, through 2.35 μg L^{-1} for chlorobenzene, 3.19 μg L^{-1} for benzene and 4.83 μg L^{-1} for trichloromethane, up to 20.37 μg L^{-1} for 2-chloroethyl vinyl ether. The total time of analysis was 12 min. In comparison with the P&T method, DAI/GC/ITS is faster, simpler to apply, and has a large dynamic range (from 20 μg L^{-1} to 20 mg L^{-1}). DAI also shows possibilities for the determination of higher boiling semivolatile compounds.

3.3 Determination of Organic Compounds by Direct Large-volume Aqueous Injection Capillary Gas Chromatography

The typical injection volume for GC is about 1 μL of sample and such a volume was used in the previously described methods. This volume is too small for DAI (without any preconcentration steps) to reach required detection limits for most of the organic pollutants of water dictated by European Union (EU) regulations. The main solution for direct water analysis is to inject much larger volumes of samples, despite water being a very difficult solvent for GC, as was previously described. Water affects the peak shape and resolution, can deactivate analytical columns and can damage the detector, causing a reduction in detection limits. To avoid these difficulties, water should be released after injection from the GC system via an early water vapor exit, before the chromatographic column and detector. The analytes are trapped on some sorbent or liquid layer inside the chromatographic system. This is the basic idea of on-line enrichment GC analysis after direct large-volume injection of aqueous samples.[65]

Zlatkis et al.[66] described a method for the quantitative determination of the trace organic compounds (2-octanone, 5-nonanone, 2-decanone, 2-undecanone, benzaldehyde, and lindane) in aqueous solutions at parts per billion (micrograms per liter) and parts per trillion (nanograms per liter) levels. Up to 400 μL of water sample was injected directly on to a bonded hydrophobic phase capillary column connected to a postcolumn [50 cm × 0.32 mm i.d. empty fused-silica open-tubular capillary column (FSOT)]. The postcolumn was not connected to the detector. The analytes were adsorbed in the main column while water was released by the open exit of the postcolumn. After water had been removed from the main column and the postcolumn, the main column was connected to the detector and adsorbed analytes were thermally desorbed, trapped in the cold trap, and analyzed by GC using the same column operating in reverse or one in series. Less than 0.1 μL of water was trapped in the cold trap. For the final determination FID or ECD (for lindane) was used.

In the case of GC/FID analysis, the Hewlett-Packard gas chromatograph used (HP 5830A) was equipped with a 50 m × 0.32 mm i.d., 0.5-μm film, bonded-phase methylsilica FSOT column, a 50 cm × 0.32 mm i.d. empty FSOT postcolumn and a cold trap (50 cm × 0.37 mm i.d. empty stainless-steel tubing in liquid nitrogen) and FID was used. Injection was performed at room temperature. After removing water (about 15 s), the main column was connected to the cold trap and heated at 200 °C for 20 min, then the oven was cooled, the outlet of the cold trap was connected to the injector and the column was reversed (the end of the column formerly connected to the injector was connected to the detector). Once the cooling from the cold trap ceased, the analysis started. The column was held isothermal for 2 min and then heated at 2 °C min^{-1}. Helium was used as the carrier gas.

In the case of GC/ECD analysis (for lindane) a Varian 3700 GC gas chromatograph equipped with an 11 m × 0.32 mm i.d., 1-μL film DB-5 (equivalent to SE-54) FSOT column as the adsorbing column, a postcolumn and a cold trap as before and a 50 m × 0.32 mm i.d., 0.52-μm film, cross-linked 5% phenyl–methylsilicone FSOT column as the analytical column. ECD was used. Injection was performed at room temperature. After removing water (about 15 s), the adsorbing column was connected to the cold trap and heated at 200 °C for 20 min, then the cold trap was disconnected from the adsorbing column and connected to the analytical column. Once cooling of the cold trap ceased, the analysis started. The temperature of the analytical column was programmed from 50 °C (initial temperature) to 240 °C at 5 °C min^{-1}. Helium was used as the carrier gas and argon with 5% methane (30 mL min^{-1}) as the makeup gas. Two columns were used to decrease the time for ECD stabilization.

Both methods required considerable manual transfer operations and were therefore laborious and time-consuming, but represented the first feasible method based on direct injection of large amounts of aqueous samples on to a capillary column. These ideas were used by other workers to realize on-line enrichment of analytes during direct analysis of large water samples.

Gerhardt and Cortes[67] improved the method for the determination of pesticides using large-volume DAI capillary GC for the determination of chlorpyrifos in well water. A Hewlett-Packard 5890 gas chromatograph was used, equipped with a 10-port valve, and a 20 m × 0.25 mm i.d. nondeactivated FSCC as the inlet (retention gap) connected via a low-dead-volume union with the analytical column (30 m × 0.25 mm i.d., 5% phenyl–methylsilicone capillary with a 0.25-μm film thickness). ECD was used. A 20-μL volume of water sample was injected via the

10-port injection valve equipped with a stainless-steel external sample loop on to the uncoated inlet. The inlet allowed complete solvent vaporization prior to reaching the analytical column. All water passed the analytical column and detector, but collecting and processing of the detector signals started after passing all water vapor. The column was heated for 15 min at 130 °C then increased to 280 °C at 20 °C min^{-1}. Helium was used as the carrier gas (6.4 mL min^{-1} at 130 °C) and argon–methane (10 : 90) at a flow-rate 32 mL min^{-1} as the makeup gas. The detection limit for chlorpyrifos was 0.22 μg L^{-1} with a linearity range from 0.9 to 18 μg L^{-1} and with high accuracy and precision. They noted that relatively large volumes of water injected into the capillary column do not affect the peak shape and resolution, even after 150 injections (3 mL of water).

Much higher volumes of water can be introduced using splitless injection with vapor overflow, as proposed by Grob et al.[68,69] for the determination of triazines (atrazine, prometryn, propazine, simazine, terbutylazine, desisopropylatrazine, and desethylatrazine). Water vapor was removed by a vapor outlet beyond the analytical column. A Carlo Erba gas chromatograph (Model 4160) was equipped with an injector containing an insert with a vaporizing chamber (80 mm × 5 mm i.d.) packed with Tenax™ TA (20–35 mesh), a 2 m × 0.32 mm i.d. precolumn coated with a 0.6-μm film of an apolar stationary phase (PEG–Superox 0.6), a 40 cm × 0.32 mm i.d. raw fused-silica column as the vapor outlet, and a 15 m × 0.32 mm i.d. FSCC coated with a 0.4-μm film of Superox and 5% Irganox 1010, and alkali flame ionization detection (AFID)/NPD was used. Up to 400 μL of water sample was injected using a syringe to the injector insert heated at 310 °C. Water vapor and volatile compounds were removed from the system by the precolumn and the open vapor outlet while the compound of interest remained in the precolumn. The temperature of the column during injection was 130 °C. After 2 min the vapor outlet was closed and the released precolumn gas was directed to the analytical column and detector. The temperature program of the column (from 130 to 240 °C at 8 °C min^{-1}) was started 5 min after injection. Hydrogen was used as the carrier gas. The detection limit for triazines was about 0.5 μg L^{-1}, so it was higher than required for routine analysis, where EU standards dictate 0.1 μg L^{-1} as the maximum acceptable concentration in drinking water.

The idea of direct injection of large amounts of water sample in an adsorbent-packed programmed temperature vaporization (PTV) injector was developed by Engewald et al.[70–73] Water was removed through the split vent while analytes were trapped on an adsorbent inside the PTV injector. Adsorbents used for such a purpose should have a large breakthrough volume for the analytes and a very low one for water, and they should also be a mechanically and thermally stable and should easily release analytes after heating. They tested Tenax™ TA, Tenax™ GR, Chemipack C18 and GCB from the point of view of breakthrough volumes for pesticides and nitroaromatic compounds. Tenax™ TA was chosen as the best sorbent with regard to the breakthrough volumes for the chosen analytes. They used a Hewlett-Packard HP 5890 Series II gas chromatograph equipped with a PTV injector (cold injection system), a glass insert packed with a 2-cm layer of Tenax™ TA (4.2 mg), a 2 m × 0.32 mm i.d. retention gap, a 25 m × 0.32 mm i.d. column with a 0.2-μm film of CP Sil 19 CB as the analytical column and ECD or NPD. ECD was used for determination of organochlorine and NPD for nitrogen- or phosphorus-containing pesticides and nitrotoluenes. Up to 500 μL or of aqueous sample were injected into the injection insert at 50 °C with a split flow of 600 mL min^{-1}. Water was removed from the insert over a 40-min period as the analytes remained on it. Elimination of water can be controlled by means of a thermal conductivity cell placed after the split vent. Desorption was realized at 280 °C for 5 min (splitless) and the analyte compounds were focused by 'cold trapping' at a column temperature of 40 °C. The column was then heated to 270 °C at 10 °C min^{-1}. The detection limits varied from 0.01 μg L^{-1} (dieldrin with ECD) to 0.5 μg L^{-1} (aldimorph with NPD). Even with extremely water-sensitive NPD, no sensitivity loss was observed after numerous analyses.

This method was applied to the determination of target and non-target pollutants in water from the Elbe River,[71] using for the final determination an MS detector in the SIM mode (for target analysis) or SCAN mode (for non-target analysis). A volume of 1 mL or more of aqueous sample was slowly injected (CIS 3 injector) into the insert with sorbent. It is very important in this technique to control the rate of sample injection.[72] Water should be completely evaporated in front of the adsorbent bed in the insert to ensure quantitative enrichment of the analytes from the gas phase. Very important also were parameters such as temperature and structure of the insert and the kind and flow-rate of the carrier gas. A simple back-flush device was developed and installed between the injector and the analytical column to avoid possible damage to the column or detector by water vapor. The detection limit of approximately 0.01 μg L^{-1} was comparable to that with conventional isolation and preconcentration techniques such as SPE or LLE connected with selective detection (ECD or NPD).

A small change to the chromatographic conditions was used by the same authors for the determination of 12 triazines and their decomposition products in water from the Elbe River.[73] A 500-μL volume of water sample was injected using the CSI 3 cooled injection system directly

into the Tenax™-packed insert of a PTV injector heated at 50 °C with an injection speed of 10 μL min^{-1} and a split flow of 600 mL min^{-1} (including 15 mL min^{-1} backflushing). Sample introduction lasted 50 min and then the split vent was closed and the analytes thermally desorbed in the splitless mode to the analytical column. For the chromatographic determination a Hewlett-Packard 5890 Series II gas chromatograph equipped with an SPB-5 column (30 m × 0.25 mm i.d. with a 0.1-μm film thickness) and helium as the carrier gas with an inlet pressure of 1.7 bar was used, with NPD. The injector was heated at 12 °C min^{-1} to 300 °C and the column was maintained at an initial temperature of 70 °C for 3.5 min, then heated to 150 °C at 15 °C min^{-1}, to 175 °C at 3 °C min^{-1}, to 280 °C at 20 °C min^{-1} and held for 2 min at 280 °C. After analysis of samples containing large amounts of nonvolatile organic and inorganic compounds, the insert must be changed frequently. This method can also be used for the determination of polychlorinated biphenyls and polycyclic aromatic hydrocarbons at parts per trillion (nanograms per liter) levels.

4 APPLICATION OF DIRECT AQUEOUS INJECTION FOR DETERMINATION OF HALOORGANIC WATER POLLUTANTS IN THE GDAŃSK DISTRICT

DAI on to capillary chromatographic columns connected with a selective electron capture detector was used for the determination of haloorganic compounds in different aqueous samples (tap, surface, swimming pool, and seawater, beers, juices, soft drinks, and physiological liquids).

4.1 Determination of Volatile Haloorganic Compounds in the Tap, Surface and Swimming Pool Waters from the Gdańsk District

The presence of volatile organohalogen compounds in tap and swimming pool water mainly originates from disinfection of the water, most often accomplished by chlorination. Even when other methods are used, such as ozonation, UV irradiation, or application of hydrogen peroxide, chlorination is necessary for water preservation in the water-mains system. About 70% of Gdańsk water is supplied from underground water intakes but 30% comes from treated water. The latter is surface water intake from Straszyn. This water, taken from the Radunia River, is treated by ozonation and at the outlet to the water-mains system by chlorination (to protect it from secondary bacteriological pollution). The water in swimming pools is also treated by chlorination. Chlorination causes very toxic, mutagenic, and carcinogenic volatile haloorganic compounds at relatively high levels (up to 100 μg L^{-1} and more) to be present in tap and swimming pool water. The World Health Organization (WHO), the EU and most individual countries, including Poland, have introduced a maximum admissible concentration (MAC) for some organohalogen compounds present in the tap water. There are first of all THMs (trichloromethane, bromodichloromethane, dibromochloromethane, tribromomethane), but also tetrachloromethane, 1,2,2-trichloroethene, 1,1-dichloroethene, 1,1,2,2-tetrachloroethene, 1,2-dichloroethane and 1,1,1-trichloroethane. The MAC varied from 0.3 μg L^{-1} for 1,1-dichloroethene (WHO, Norway) to 100 μg L^{-1} (EU, WHO, USEPA, UK) for total trihalomethanes (TTHMs) and 350 μg L^{-1} for TTHMs (Canada). Typical concentrations of trichloromethane (chloroform), the compound most frequently present in the water treated by chlorination, varied from 1 to 30 μg L^{-1}; 30 μg L^{-1} is the MAC in the directives of the WHO, Poland and UK for chloroform in tap water. DAI on to a capillary GC column with ECD is a suitable method for the determination of organohalogen compounds in this range of concentrations. This method requires a special injector allowing cold on-column injection and special capillary columns. A nonvaporizing, septumless, cold on-column injector with secondary cooling (Grob type) fulfilled nearly all requirements for the good introduction of the sample on to the chromatographic column.

The construction of such an injector, produced by Carlo Erba, is shown in Figure 2.[17] The aqueous sample (1–2 μL) was introduced directly in to the oven-thermostatted capillary GC column inlet using a syringe with an outer diameter of the needle smaller then the inner diameter of the column. Secondary air cooling of the inlet of the column prevented sample evaporation in the syringe needle (including its tip). The evaporation started after deposition of the sample on the column wall. The sample was mechanically transferred instead of being evaporated, so high-boiling components did not remain in the syringe needle. The secondary cooling was switched on only before and during the sample injection. The primary cooling of the injector body worked permanently. The secondary cooling permitted rapid cooling of the bottom part of the injector attached to the oven, preventing discrimination of compounds at the syringe tip. It also allowed the introduction of a larger volume of sample, which permitted a decrease in the detection limits. The sample was injected at an injector temperature lower, than the solvent boiling point, but at an oven temperature higher than the solvent boiling point.

Nonvolatile inorganic and organic compounds can gradually accumulate at the column inlet which will

Figure 2 Schematic diagram of nonvaporizing septumless, cold on-column injector: 1 = oven wall; 2 = secondary air cooling; 3 = principal air cooling system; 4 = carrier gas inlet; 5 = stainless-steel rotating valve; 6 = valve seal; 7 = syringe; 8 = valve lever; 9 = upper part of injector; 10 = column seal; 11 = bottom part of injector; 12 = cooling jacket; 13 = capillary column.

make the resolving power of the column deteriorate. To prevent this, readily exchanged, deactivated, noncoated precolumns (2 m × 0.32 mm i.d.) connected to the analytical column through a zero-dead-volume fitting were used. Following a specified number of analyses, the precolumn can be completely exchanged or part of it can be broken off. The precolumns play another important role: they serve as a so-called retention trap, narrowing the chromatographic bands of the analytes. The sample volume during fast injection spreads in the column inlet, flooding it and causing 'band broadening in space', so it is necessary to reconcentrate the broad inlet band. The band broadening in space depends on the temperature, the speed of injection, and the volume injected. In the precolumn all compounds present in the gaseous phase migrate with the same speed owing to the lack of any interaction. In the main column coated with a stationary film of nonpolar phase, the analytes, interacting with the stationary phase, are focused and water, which does not react with the stationary phase, is washed out freely. To prevent retention of water the precolumn and the analytical column should be deactivated. The film of the stationary phase should also be immobilized by cross-linking.

During the chromatographic process, water was eluted before the analytes owing to the use of an inert column coated with a thick layer (ca. 5 μm) of nonpolar stationary phase which resulted in rapid and complete elution of water and sufficient retention of the analyte organohalogen compounds. Methylsilicones (DB-1) were used as nonpolar stationary phases. To improve separation, methylsilicone stationary phases modified with vinyl groups (PS-255, 1% vinyl groups) were applied. Capillary columns 30 m long with i.d. ca. 0.5 mm were used. Longer columns provided improved resolution but at the expense of sensitivity. Isothermal runs at about 102–105 °C were employed. As a result of the high sensitivity of the ECD instrument employed, the stationary phase in the analytical column was immobilized through cross-linking and chemical binding to the column wall.

The electron capture detector was operated at 350 °C, which minimizes the residence time of water in the detector, thus improving the sensitivity of the detector. For the identification of the analytes and for quantitative analysis of other organic compounds, GC/MS was used. For the determination of volatile organohalogen compounds (trichloromethane, bromodichloromethane, dibromochloromethane, tribromomethane, tetrachloromethane, trichloroethene, tetrachloroethene, dichloromethane, 1,1,1-trichloroethane, 1,1,2,2-tetrachloroethane), DAI into a capillary column and ECD were used.[75–81] A Carlo Erba Vega 6180 gas chromatograph was applied with ECD (ECD 40/400). The chromatographic conditions were as follows: a 30 m × 0.32 mm i.d. FSCC, coated with bonded 5-μm apolar DB-1 phase (J&W Scientific) or slightly more polar PS-255 (with 1% vinyl groups); a 2 m × 0.32 mm i.d. fused-silica precolumn; temperature program, 103 °C isothermal; injection system, cold on-column with secondary cooling (20 s before injection); detection, ECD at 350 °C with pure nitrogen (99.999%) as the makeup gas (30 mL min^{-1}); carrier gas, hydrogen at 0.4 m s^{-1}; and injection volume, 2 μL. The retention times, standard deviation ($P = 95\%$; $n = 7$, concentration about 20 μg L^{-1}), and detection limits of volatile organohalogen compounds for the applied columns DB-1 and PS-255 are listed in Table 2. The detection limits were calculated as three times the baseline random noise level.

The DAI/ECD technique has been successfully used for the determination of volatile organohalogen compounds containing one or two carbon atoms (the products of chlorination of humic substances; THMs) in tap water,[75,76] swimming pool water,[77] and surface water.[76,78–81] Typical results of analysis are listed in Tables 3, 4 and 5. An example of a chromatogram of volatile organohalogen compounds obtained using this method is presented in

Table 2 Retention times, standard deviations ($P = 95\%$; $n = 7$) and detection limits of volatile organohalogen compounds for different columns

Figure 4 Changes in chloroform concentration in the tap water from different sampling sites in the Gdańsk area during the period 1993–97.

water, which of the districts of Gdańsk were supplied with water treated by chlorination. Only in 1993, in some cases (Gdańsk Suchanino), did the content of chloroform exceed the Polish and WHO standards. At the same time the concentrations of THMs in all districts supplied by surface water intake from Straszyn were relatively high. After changing the water treatment in this water intake from chlorination to ozonation and introducing water filtration with a carbon filter, these concentrations decreased significantly.

The investigations on tap and surface waters were carried out using a DB-1 chromatographic column, on which, unfortunately, bromodichloromethane and trichloroethene were determined as the sum. Bromodichloromethane is a typical product of humic acid chlorination, whereas trichloroethene originates from industrial sewage. It was confirmed by GC/MS that in the tap water in the Gdańsk Żabianka district trichloroethene was present at relatively high concentration (but not exceeding any standards). A similar high concentration of trichloroethene were found in the underground water intake in Sopot, from which this district of Gdańsk was supplied. Unfortunately, some underground water intakes are polluted by industrial sewage, in this case probably from laundries. Trichloroethene was found also in the Kacza River, flowing across the densely populated district of Gdynia, and in the seawater at Gdynia Orłowo, near the mouth of the Kacza River.

The highest concentration of volatile haloorganic compounds was found in the water from the swimming pool (swimming pool of the Technical University of Gdańsk in Gdańsk Wrzeszcz). This water is intensely chlorinated for sanitary purposes. Here a wide range of haloorganic compounds was found: not only THMs, but also dichloromethane, tetrachloromethane, 1,1,1-trichloroethane, etc. The occurrence of bromoorganic compounds was due to the fact that the raw water contained small amounts of bromides. During chlorination, free bromine is formed, which reacts with organic compounds to form organobromine compounds.

The DAI/GC/ECD technique proved to be a good and very useful method for the determination of volatile haloorganic compounds in tap and swimming pool water owing to its simplicity (no isolation and preconcentration steps are necessary), repeatability, reduction of the possibility of sample contamination by the solvent or sorbent used, reduction of possible losses of volatile compounds during additional steps, and low detection limits (0.002–0.1 $\mu g\,L^{-1}$, only for dichloromethane 1 $\mu g\,L^{-1}$) depending on the percentage of halogen in the compound. The detection limit of the method is related to the amount of the analyte in the sample injected on to the column and the volatility of the analytes. On the basis of presented investigations, Biziuk and Czerwiński[82] elaborated a proposal for a Polish Standard Method (PrPN-C-04549-1) for the determination of dichloromethane, trichloromethane, tetrachloromethane, bromodichloromethane, dibromochloromethane, tribromomethane, trichloroethene, tetrachloroethene, 1,1,1-trichloroethane, and 1,1,2,2-tetrachloroethane in water by GC using direct injection of the sample.

4.2 Application of Direct Aqueous Injection for Determination of Semivolatile and Nonvolatile Haloorganic Water Pollutants

DAI on to capillary chromatographic columns connected with selective ECD has also been used for the determination of semivolatile and nonvolatile haloorganic compounds in different aqueous samples.

In the case of the simultaneous determination of volatile and semivolatile compounds, a longer analytical column with an appropriate oven temperature program and a thinner film layer in the analytical column have to be used. Wolska et al.[79] used for the determination of 12 volatile and semivolatile organohalogen compounds (from 1,2-dichloroethane to dichlorobenzenes, trichlorobenzenes and hexachlorobutadiene) cold on-column injection (2 μL), a precolumn (2 m × 0.32 mm i.d.) and an Rtx-624 (60 m × 0.32 mm i.d.) column coated with a 1.8-μm film of stationary phase (6% cyanopropyl–94% dimethylpolysiloxane). The oven temperature program was as follows: 104 °C for 4 min, then heated to 110 °C at 3 °C min^{-1} and to 200 °C at 5 °C min^{-1} and held for 1 min at 200 °C. The detection limit varied from 0.02 $\mu g\,L^{-1}$ for tetrachloromethane and trichloroethene, through 0.04 $\mu g\,L^{-1}$ for trichloromethane to 1.2 $\mu g\,L^{-1}$ for 1,2-dichlorobenzene. The analysis was carried out on water from the Vistula River and Reda River.

In the method routinely used in the laboratory of SAUR–Neptun Gdańsk (water supply and sewage system for Gdańsk) for the determination of volatile and semivolatile haloorganic compounds in tap water, an Rtx-Volatiles column (60 m × 0.32 mm i.d.) coated with a 3-μm film and an oven temperature program (104 °C for 1 min, then heated to 160 °C at 2.5 °C min^{-1}) were used. A typical chromatogram of 15 compounds obtained in this laboratory is shown in Figure 5.

It was also possible to use the DAI/GC/ECD method for the determination of pesticides but at high concentrations. This method was performed for the determination of the pesticide destruction ratio during their chemical oxidation in the aqueous phase (our work). Cold on-column injection (2 μL) and an Rtx-5 capillary column (30 m × 0.25 mm i.d.) coated with a 0.25-μm film (5% diphenyl–95% dimethylpolysiloxane) were used. The oven temperature program was as follows: from 60 to 100 °C at 30 °C min^{-1} and to 280 °C at 10 °C min^{-1}, then held for 10 min at 280 °C. For lindane, *p*,*p*′-DDT and methoxychlor the detection limit was about 0.1 $mg\,L^{-1}$.

4.3 The Combination of Thin-layer Headspace Technique and Direct Aqueous Injection for Determination of Haloorganic Water Pollutants

The application of the DAI/GC/ECD method to samples with very complex matrices containing numerous

Figure 5 Typical chromatogram of volatile organohalogen compounds (DAI/GC/ECD, temperature programming). Peaks: 1 = 1,1-dichloroethene; 2 = dichloromethane; 3 = 1,2-dichloroethene; 4 = 1,1-dichloroethane; 5 = trichloromethane; 6 = 1,1,1-trichloroethane; 7 = tetrachloromethane; 8 = trichloroethene; 9 = bromodichloromethane; 10 = 1,1,2-trichloroethane; 11 = tetrachloroethene; 12 = dibromochloromethane; 13 = 1, 1, 1, 2-tetrachloroethane; 14 = tribromomethane; 15 = 1,1,2,2-tetrachloroethane.

inorganic salts or nonvolatile organic compounds and also for low concentrations of analytes creates many problems. Only small amounts of the samples (2 μL) are introduced into the column, which causes a high detection limit. The detection limit of the DAI/GC/ECD method for volatile haloorganic compounds is sufficient for tap and swimming pool water treated by chlorination and for polluted surface waters, but insufficient for unpolluted underground or surface waters. Direct injection of aqueous samples into a GC column cannot be performed for complex matrices such as seawater, wastewater, surface water rich in humic acids, body fluids, mineral waters, soft drinks, beers, and juices. Inorganic salts and nonvolatile organic compounds deposited in the precolumn retain water, causing broadening of the water peak and an increase in the retention time for the analytes. These contaminants can be slowly transferred to the main column and to the detector, affecting the peak shape, deactivating the column, and changing the chromatographic conditions of the column and detector. These drawbacks can be eliminated by application of a combination of the thin-layer HS technique with the DAI method. This combination allows the preconcentration of analytes in the aqueous phase and the matrix to be changed from a complex mixture of inorganic and organic compounds to a solution of analytes in pure water. The thin-layer countercurrent headspace (TLHS) method introduced by Kozłowski et al.[83–96] is based on passing volatile compounds from the thin layer of aqueous sample to a countercurrently flowing stream of purified air.

The main part of the apparatus for TLHS is a vertically positioned, spirally wound, thermostated glass tube (2 m × 7 mm i.d.) shown in Figure 6. The sample was introduced on the top of the tube and flowed down in the form of a thin film, from which analytes together with water vapor were transferred to the gaseous phase and transported to the final determination. This approach can be used as a different method for the determination of volatile organic compounds, for the determination of total parameters and individual compounds, and also for preparing the sample for DAI analysis.[90–96] In such a case two TLHS columns have to be used. In the first column, thermostated at a high temperature (up to 90 °C), the analyte compounds were transferred, together with water vapor to a stream of air, and in the second column, cooled at 10–11 °C, water vapor was condensed together with the analytes. The condensate leaving the second column was taken for DAI/GC/ECD analysis. There are very important advantages of such a procedure: the compounds of interest are isolated from the complex aqueous matrix and preconcentrated in pure water, and it allows determination of volatile organohalogen compounds in beverages[94] (mineral waters, juices, soft drinks) and biological fluids (urine).

Figure 6 Column for countercurrent TLHS in a spiral tube. 1 = sample inlet; 2 = outlet of the gas stream containing the liberated analytes (to the combustion tube); 3, 4 = outlet and inlet of water from thermostat, respectively; 5 = inlet of purified air; 6 = sample outlet.

5 CONCLUSIONS

DAI is the simplest method for the determination of organic water pollutants that avoids isolation and preconcentration steps.[4,16,17,74] This method is also very fast and easy to automate. The DAI/GC/ECD method is very useful for the determination of volatile and semivolatile organohalogen compounds in tap, swimming pool and surface waters and also for the determination of pesticides and other compounds which are present in water at sufficient concentrations for detection. The method avoids the problems associated with using solvents (toxic and expensive) and incomplete recovery of the analytes during their isolation from the aqueous phase, the effect of potential contaminants when using solvent or SPE, and losses of the analytes during the enrichment step.

The application of the DAI/GC/ECD method to samples with very complex matrices containing numerous inorganic salts or nonvolatile organic compounds, and for low concentrations of analytes, creates many problems. These drawbacks can be eliminated by the application of a combination of the thin-layer HS technique and the DAI method. This combination allows the preconcentration of analytes in the aqueous phase and changes the matrix from a complex mixture of inorganic and organic compounds to a solution of analytes in pure water.

The best method for the determination of pesticides and other nonvolatile compounds is the direct injection of large amounts of water samples in an adsorbent-packed PTV injector with removal of water vapor from the GC system via an early water vapor exit, before the chromatographic column and detector.

ABBREVIATIONS AND ACRONYMS

AED	Atomic Emission Detection
AFID	Alkali Flame Ionization Detection

When capillary gas chromatography (GC) is coupled with atomic emission detection (AED), mixtures of volatile and semivolatile organic compounds are first separated based on different retention in a capillary GC column, whereafter the separated compounds are introduced directly into a helium (or argon) plasma. The high temperature of this plasma results in atomization of the separated compounds followed by excitation of the constituent atoms. From the excited states, the atoms emit light of characteristic wavelengths which are monitored continuously during the chromatographic separation by an optical spectrometer. This results in element-selective chromatograms, where all elements from the periodic table (except helium or argon) may be monitored selectively with a simple change of wavelength on the spectrometer. With the use of multichannel spectrometers, several elements may be monitored simultaneously resulting in multielemental detection. Both nonmetallic and metallic elements are detected with a very high selectivity. This enables environmental contaminants containing heteroatoms to be determined in dirty extracts without extensive sample cleanup. However, since detection limits (DLs) in GC/AED range from 1–100 pg s^{-1}, extensive analyte enrichment is often required prior to environmental analysis. Because the separated compounds are atomized within the plasma, only minor structural variations are observed for the detector responses. This, in combination with the multielemental capability, enables estimation of empirical formulas for each of the separated compounds, which may be utilized to support identification of environmental micropollutants. In addition, the structure-independent detector responses enable simplified calibration for quantitative purposes because different compounds may be quantified based on a single elemental calibration curve.

1 INTRODUCTION

When capillary GC is coupled with AED, high separation power and simultaneous multielemental detectability are combined into an attractive (hyphenated) analytical technique GC/AED. Volatile and semivolatile organic compounds present in complex mixtures are separated in the GC and subsequently introduced into a small helium (or argon) plasma placed in continuation of the GC column (Figure 1). The high temperature of this discharge (3000–10 000 K) results in atomization of each of the separated compounds followed by excitation of the constituent atoms to higher electronic states. Light of wavelengths characteristic of the elements introduced are emitted by the excited atoms as they undergo transitions to lower energy levels. With an optical spectrometer, emission light for the elements of interest is selected and measured continuously resulting in element-selective chromatograms. Since atomic lines are narrow and often intense, GC/AED provides high elemental selectivity and acceptable sensitivity. Theoretically, every element from the periodic table (except helium or argon) may be detected by a simple change of wavelength. Since all emission lines are present in the plasma simultaneously, either single- or multichannel detection is possible. Compared with the array of selective detectors responding to one or two elements (e.g. flame photometric detection (FPD), nitrogen–phosphorus detection (NPD), sulfur chemiluminescence detection (SCD), oxygen-flame ionization detection (O-FID)), this multielemental capability represents a major improvement in terms of versatility.

The attractive features of GC/AED were reported for the first time in 1965 by McCormick et al. with an atmospheric pressure argon microwave induced plasma (MIP) coupled to packed column GC.[1] Although the period 1965–1975 also saw research into direct current discharges,[2] most GC/AED research was carried out

Figure 1 Principle of AED in capillary GC.

with systems utilizing argon MIPs or reduced-pressure helium MIPs. Unfortunately, the excitation potential of the argon plasmas was insufficient for the detection of several nonmetallic elements, and the evacuation equipment required to produce low-pressure helium plasmas was complex. Therefore, the introduction of the TM_{010} cavity by Beenakker in 1976 represented a distinct technical improvement in the field of GC/AED because this permitted helium MIPs to be sustained at atmospheric pressure.[3] Implementation of the TM_{010} cavity by other workers was reported from 1978–1980, which almost terminated the interest for reduced-pressure MIP systems.

Although most effort has been focused on MIP systems, after 1980, successful GC detection was accomplished with several alternative discharges, including a 25 kHz helium after-glow device,[4] a 350 kHz radio frequency helium plasma,[5,6] a 60 Hz alternating current helium plasma,[7] a 27.18 MHz capacitively coupled helium plasma,[8] and a 27.12 MHz stabilized capacitively coupled helium plasma.[9] In addition, with argon at atmospheric pressure, direct current plasmas (DCPs)[10] and inductively coupled plasmas (ICPs)[11] have been evaluated, but both plasma systems suffered from poor excitation characteristics for several important nonmetallic elements and from a large consumption of high-purity argon.

GC/AED was carried out solely with laboratory-built instrumentation until the late 1970s, when the first commercial atomic emission detector for GC was introduced by Applied Chromatography Systems. This equipment was based on a reduced-pressure helium MIP and a Rowland circle spectrometer with 12 fixed channels for simultaneous multielement detection.[12] However, the popularity was low, and even a modified version based on an atmospheric-pressure helium MIP sustained in a TM_{010} cavity was implemented only in a limited number of research laboratories. In 1989, a second attempt was made by Hewlett-Packard to commercialize an atomic emission detector for GC. A totally automated benchtop system was introduced, which utilized an atmospheric-pressure helium MIP for analyte excitation and a photodiode array for the monitoring of atomic emission.[13,14] The photodiode array, which covered the wavelength range from 160–800 nm in 25 nm portions, provided simultaneous multielement detection, multipoint spectral background correction, and elemental confirmation by atomic emission spectra. From the same company, an improved version of this atomic emission detector was recently introduced as a less expensive second-generation instrument with enhanced sensitivity. The two commercially available GC/AED systems from Hewlett-Packard have increased the interest for the technique substantially, and several environmental applications of GC/AED have emerged in recent years. Below, advantages and limitations of GC/AED for environmental analysis are discussed and some of the most interesting environmental applications are reviewed. Principal attention is focused on results obtained with the commercial system, while only a few data from home-built systems are included owing to the difficulties of reproducing this type of complex instrumentation.

2 SELECTIVITY AND SENSITIVITY CONSIDERATIONS

Environmental samples are typically very complex with a large number of matrix components, among which

the analytes of interest are present at low concentration levels. Therefore, both selectivity and DLs are important parameters for the successful determination of most environmental micropollutants. In this section, attention will be focused on both of these parameters in order to understand the advantages and the limitations of GC/AED for environmental analysis.

As atomic emission lines are very narrow, overlap from different elements is normally not a problem in GC/AED. However, emission spectra from helium plasmas utilized for GC/AED normally also contain molecular bands (originating from incomplete atomization or from atomic recombinations) which are generally relatively broad. Unfortunately, these may interfere with the atomic lines of interest causing false positive signals (interferences) or negative baseline excursions. Therefore, in order to realize the full potential of the narrow atomic emission lines and to ensure high elemental selectivity, spectral background correction is of great importance in GC/AED.[15] With commercial instrumentation, this is accomplished utilizing a photodiode array for the optical measurements, where continuous multipoint data correction results in very high selectivity for the most important elements found in GC amenable compounds. This is illustrated in Table 1, where the selectivity for several metallic and nonmetallic elements has been determined relative to carbon. With chlorine as an example (selectivity value of 27 000), 27 000 ng carbon (from a hydrocarbon) is required to produce the same signal on the chlorine channel as obtained from 1 ng of chlorine. For practical work with environmental samples, the high elemental selectivities obtained by GC/AED is obviously a major advantage. Organic micropollutants containing heteroatoms (such as Cl, Br, S, Sn, and Hg) may be selectively detected even in very complicated extracts where the resolving power of GC is insufficient. This is illustrated in Figure 2, where GC/AED was utilized for the detection of polychlorinated biphenyls (PCBs) in a highly contaminated marine sediment.[17] In spite of the high background from a crude oil matrix, the PCBs emerged as distinct peaks in the highly selective chlorine trace. Thus, the PCBs were easily located in the chlorine trace and quantitative analysis was rapidly performed because no interferences distorted the peak areas. The highly contaminated sediment sample was also exposed to analysis by GC/MS,[17] but this technique suffered from serious interference when operated both in the low- and high-resolution modes (Figure 2). Thus, although selected ion monitoring was utilized, localization and quantitation of the PCBs were almost impossible based on the GC/MS results.

Table 1 Selectivities and DLs for the second generation of the commercial GC/AED system from Hewlett-Packard[16]

Element	Wavelength (nm)	Selectivity[a]	DL ($pg\,s^{-1}$)[b]
C	193	–	0.6
H	656	–	0.2
F	690	166 000	10.7
Cl	837	27 000	13.0
Br	827	15 000	15.3
N	174	7 000	4.6
O	171	18 000	43.4
S	181	37 000	0.6
P	186	14 000	0.5
Sn	326	3 300 000	0.4
Hg	254	258 000	0.6
Pb	406	286 000	0.2

[a] Selectivities were defined as the ratio of the response per nanogram of element to the response per nanogram of carbon.
[b] DLs were defined as the amount of element required to produce a peak twice the noise level, divided by the full width at half-height of the peak in seconds.

In addition to selectivity considerations, DLs of GC/AED are of great importance in evaluating the potential for environmental analysis. As illustrated in Table 1 for the commercial system, DLs of GC/AED are generally at the low picograms per second level. Unfortunately, values for the different elements vary by a factor of 200 depending on several factors such as atomic line intensity, excitation potential, and natural background in the plasma. For oxygen, an important element in environmental micropollutants, the DL is relatively high and therefore the practical utility of O-selective detection by GC/AED is strongly limited for environmental applications. DLs for chlorine and bromine, which are important elements within environmental monitoring, were relatively high for the first generation of the Hewlett-Packard GC/AED, but significantly lower values have been reported especially for chlorine with the new version.[17] Thus, especially with the second generation of GC/AED, the technique may be an alternative for the determination of pesticides and polyhalogenated compounds such as PCBs (discussed in detail in sections 5.4 and 5.5). For sulfur, phosphorus, and most of the metallic elements, DLs are at the low picograms per second level supporting the idea that compounds containing these elements may be monitored at relatively low concentration levels by GC/AED.

From the discussion above, high elemental selectivity is the major advantage of GC/AED for environmental analysis. Thus, organic micropollutants containing heteroatoms may be selectively detected in complicated samples without serious interference, and time-consuming sample cleanup may be reduced. However, for some elements DLs are relatively high, which may limit the applicability of the technique or which may call for extensive analyte preconcentration in order to match

Figure 2 GC analysis of an extract of a highly contaminated marine sediment by (a) GC/AED in the Cl-selective mode and by GC/MS in the (b) low- and (c) high-resolution modes (summarized ion selective chromatograms for molecular ions of PCBs).[16] (Reproduced from *Chromatographia*, **43**, 44–52, 1996, with permission from Vieweg.)

the low concentration levels typical for environmental samples.

3 COMPOUND INDEPENDENT CALIBRATION FOR QUANTITATIVE ANALYSIS

During detection, the compounds separated by GC are atomized within the AED and emission is measured from excited atoms. Therefore, in theory, the detector response per element (area counts per nanogram of element) should be independent of the molecular structure from which it originated. For quantitative purposes, this should enable universal calibration where a large number of different compounds are quantified based on a single elemental calibration curve (e.g. for chlorine) obtained for a randomly selected reference compound. Unfortunately, for practical work, this type of universal calibration is somewhat complicated by discrimination during GC injection and by chemical reactions/spectral interferences occurring within the plasma. As illustrated in Table 2 for some PCBs, deviations up to 10% occurred when the chlorine signal from a standard solution of PCB no. 128 was utilized for the quantitation of the other PCBs included in Table 2.[17] Nevertheless, for the determination of organic micropollutants, purchase of reference material is expensive and in several cases, reference standards for the compounds are not commercially available. Thus, for applications where very high accuracy is not required, analysis by GC/AED and universal calibration may be a very fast and simple concept to obtain quantitative data.

Figure 2 (*Continued*)

4 ESTIMATION OF MOLECULAR FORMULAS

With GC/AED operated in the multielement selective mode, where several different elements are monitored simultaneously, the resulting element-selective chromatograms directly give qualitative information about the constituent elements for each of the separated compounds. With peak no. 5 in Figure 3 as an example, where halogenated alkylbenzenes were detected in nickel industry wastewater, the element-selective chromatograms proved that C, H, and Cl were all present in the compound, while Br was not a constituent of this particular compound. In addition to this, since elemental responses are almost independent of molecular structures (as discussed in section 3), the element-selective chromatograms also contain quantitative information about the elemental composition for each of the separated compounds. Thus, based on simple calibration and multielemental detection, empirical/molecular formulas may be calculated based on GC/AED. This is illustrated in Table 3, where the molecular formula for several halogenated alkylbenzenes present in nickel refinery wastewater (Figure 3) was calculated based on dichlorobenzene as reference.[18] Although deviations up to 30% from correct values were observed in some cases, the approximate empirical formulas were utilized to support rapid analyte identification. For target compound analysis, where analyte identification principally is based on retention time data obtained with standard solutions of the components of interest, empirical formulas calculated by GC/AED may significantly improve the reliability of analyte identifications. For nontarget purposes, however, where retention time information normally is not available, identification based solely on GC/AED is unreliable and should be based principally on GC with mass spectrometric or infrared detection.[19,20] Although identification is based on GC/MS, results from GC/AED may be of great interest to complement mass spectral data. This is illustrated in Figure 4, where chromatograms from both GC/MS and GC/AED analysis of an extract of a pulp mill effluent are shown.[19] The compound corresponding to peak no. 4 was identified as tetrachlorothiophene (C_4Cl_4S) based on

Figure 2 (*Continued*)

library search on the GC/MS system. This conclusion was supported by the GC/AED results proving that C, Cl, and S were present in the compound while H and O were absent. For peak no. 5, no library mass spectrum was available and manual interpretation was necessary. The mass spectrum (Figure 4) revealed the presence of three chlorine atoms and a molecular mass of 216. Unfortunately, the mass spectrum also contained fragments from co-eluting compounds, and further interpretation was therefore difficult. However, the GC/AED results

Table 2 Normalized chlorine response factors (area counts per nanogram) for selected PCB congeners

Congener number	No. of chlorine atoms	Normalized chlorine response factor[a]
31	3	0.974
53	4	1.049
105	5	1.000
128	6	0.966
185	7	1.018
194	8	1.050
209	10	1.059

[a] Chlorine response factors normalized against congener no. 105.

demonstrated that C, H, S, Cl, and O were all present in the compound. Based on this additional information, and assuming also that peak no. 5 was a thiophene, the compound contained one S atom, three Cl atoms, and at least four C atoms (C_4Cl_3S corresponds to 185 mass units). The remaining mass difference up to 216 was 31, and for this part of the molecule, the GC/AED results proved the presence of a single O atom. The 31 mass units probably corresponded to a methoxy group ($-OCH_3$), and the compound was suspected to be an isomer of trichloromethoxythiophene.

5 ENVIRONMENTAL APPLICATIONS

Based on the discussion in sections 2, 3, and 4, the major limitation of GC/AED is related to relatively high DLs for some of the nonmetallic elements, while the major advantages are related to the high selectivity, the multielemental capability, and the possibilities of performing universal calibration (quantitative analysis) as well as estimating empirical/molecular formulas. Based on these characteristics, important environmental applications will be reviewed in this section (section 5).

5.1 Tin-containing Compounds

Substantial research has been reported on the GC/AED determination of organotin compounds originally used as antifouling paints on ships, slimicides, pesticides, and as stabilizers in polyvinyl chloride. Thus, organotin compounds have been determined in sediments,[21–27] soil,[23] water,[22,26–31] and biological samples[21,24,25] by GC/AED. An example is illustrated in Figure 5, where tin-organic compounds were detected in mussel tissue.[24] Excellent selectivity has been reported for GC/AED operated in the Sn-selective mode. For complex environmental samples, the selectivity of GC/AED significantly exceeded both GC/MS[26] and GC/FPD.[21] In addition to the high selectivity, the presence of

Table 3 Molecular formulas determined by GC/AED for six halogenated alkylbenzenes present in nickel refinery waste water[18]

Peak no.	Correct formula	Formula determined by GC/AED
1	$C_9H_9Cl_3$	$C_{8.8}H_{8.3}Cl_3$
2	$C_9H_{10}Br_2$	$C_{11.3}H_{13.2}Br_2$
3	$C_9H_{10}Br_2$	$C_{8.1}H_{7.9}Br_2$
4	$C_9H_{10}Br_2$	$C_{7.3}H_{7.2}Br_2$
5	$C_9H_9Cl_3$	$C_{9.0}H_{8.6}Cl_3$
6	$C_9H_9Cl_3$	$C_{8.2}H_{7.9}Cl_3$

tin was confirmed in the case of GC/AED utilizing atomic emission spectra obtained by the photodiode array and stored during each GC analysis.[21] The DL of the commercial GC/AED has been reported to be comparable with GC/FPD,[27] which is the most popular detector for Sn-selective detection. GC with atomic absorption spectrometry has also been utilized for Sn-selective detection, but this technique was 1–2 orders of magnitude less sensitive than GC/AED.[24,27] When operated in the selected ion monitoring mode, GC/MS was found to provide only slightly better DLs than GC/AED[26] supporting the idea that GC/AED is highly attractive for Sn-selective detection. With GC/AED, organotin compounds have been detected down to the 0.1-ng L^{-1} level in water samples[28–31] and to the 0.2-ng g^{-1} level in sediments.[23,25] While quantification by GC/MS required references for each of the compounds of interest, several tin-organic compounds

(b)

Figure 4 (*Continued*)

have been quantified by GC/AED utilizing universal calibration.[26,28] In addition, tin-organic compounds have been identified based on empirical formulas calculated from GC/AED results.[22]

5.2 Lead-containing Compounds

In addition to tin-organic compounds, GC/AED has been successfully applied for the determination of lead-containing compounds in water,[32–34] road dust,[34] and snow.[35] With emphasis on organolead compounds used as antiknock additives in gasoline, GC/AED was found to be substantially more sensitive than GC coupled with atomic absorption spectrometry,[32] the latter of which has been the most popular technique for Pb-selective detection in capillary GC. Thus, with GC/AED, organolead compounds were detected at the 0.1–2-ng L^{-1} level in water[32,33] and down to the femtogram per gram level in snow.[35] As for tin, GC/AED is very attractive also for lead compounds because of excellent selectivity and sensitivity.

5.3 Mercury-containing Compounds

Organomercury compounds have been utilized in paints, wood preservatives, paper, and pesticides, and this class of

Figure 5 GC/AED analysis of an extract of mussel tissue in the Sn-selective mode.[24] (Reproduced by permission LC–GC International, Advanstar Communications Inc.)

compounds is of great importance within environmental monitoring. GC/AED operated in the Hg-selective mode has been used for the determination of organomercury compounds present in biological samples[36,37] and in water.[38] Compared with gas chromatography/electron capture detection (GC/ECD), which is in frequent use for the detection of organomercurals, the selectivity was superior utilizing GC/AED while DLs of the two detectors were comparable.[36] Thus, with GC/AED, organomercury compounds were detected down to the low nanogram per liter level in water.[38]

Owing to the simultaneous multielement capability of GC/AED, several reports have emerged where tin, lead, and mercury compounds have been determined simultaneously in biological material,[39] soil,[40] and water.[41] An example of this is illustrated in Figure 6, where both organotin and organolead compounds were found in river water.[41] This, in addition to excellent selectivity and sensitivity, suggests that GC/AED is a very attractive technique for the determination of organometallic compounds in environmental samples.

Figure 6 GC/AED analysis of an extract of river water in the Hg-, Sn-, and Pb-selective modes.[41] (Reproduced by permission of The Royal Society of Chemistry.)

5.4 Pesticides

Several publications have focused on the GC/AED determination of pesticides in environmental and agricultural samples. This broad class of compounds, which are produced industrially as agricultural chemicals, are particularly good candidates for GC/AED analysis since they are rich in heteroatoms such as chlorine, bromine, fluorine, phosphorus, sulfur, nitrogen, and oxygen. Thus, pesticides have been detected in different vegetables,[42–46] soil,[47,48] and water[48–53] utilizing GC/AED. An example is illustrated in Figure 7, where several pesticides were detected in an onion sample by GC/AED.[43] Excellent selectivity has been reported in the chlorine-selective mode for different pesticides present in agricultural products, while the established ECD (electron capture detection) and electrolytic conductivity detection (ELCD) devices suffered from matrix-related interferences.[42,43] Thus, a GC/AED screening method has been tentatively approved by the US Environmental Protection Agency for inclusion in the Update IV of the SW-846 methods.[48] In addition, GC/AED was found to provide accurate quantitation based on a single chlorine calibration curve (universal calibration). Unfortunately, the pesticide DL in the chlorine-selective mode of the first generation of the commercial GC/AED system was found to be a factor of 10^2–10^4 higher than for GC/ECD.[54] Thus, extensive analyte preconcentration was required to detect organochlorine pesticides by GC/AED at the 0.01 ppm level in agricultural matrices.[43] With the second generation of the commercial GC/AED system, the sensitivity

Figure 7 GC/AED analysis of an extract of onion in the C-, Cl-, Br-, S-, N-, and P-selective modes.[43] 4 = γ-HCH, 6 = parathion, 9 = bromophos ethyl, 10 = α-endosulfan, 11 = β-endosulfan, and 12 = endosulfan sulfate. (Reproduced from the *Journal of High Resolution Chromatography*, **16**, 539–548, 1993, with permission from Hüthig-GmbH.)

problem is expected to decrease, and GC/AED pesticide DLs (concentration units) have been improved by a factor of 100 compared with 1-ml injections by performing large volume injections (100 ml) with a solvent vapor exit in front of the analytical column.[49,52]

In addition to chlorine-selective detection, GC/AED in the bromine-, phosphorus-, sulfur-, and nitrogen-selective modes has been reported for the determination of pesticides. While bromine-selective detection is used only occasionally, several papers have emerged utilizing phosphorus-selective detection. The selectivity has been reported to be excellent in different agricultural matrices, and superior to results with both NPD and FPD detection.[42,43] The phosphorus DL of GC/AED was found to be comparable with FPD,[43] but significantly higher than for NPD.[54] Nevertheless, organophosphorus pesticides have been detected down to the 0.01-ppm level in plant foodstuffs by GC/AED utilizing 1 ml injections.[42,43] With 100 ml injections, even lower DLs have been obtained in the phosphorus-selective mode utilizing a solvent vapor exit in front of the analytical column.[51,52] Quantitative results from GC/AED were in excellent accord with data from NPD, and GC/AED was also found to enable accurate quantitation based on universal calibration in the phosphorus-selective mode.[48]

Some of the commercial pesticides also contain sulfur, and these may be selectively detected by GC/AED operated in the sulfur-selective mode. With the commercial GC/AED system, which is relatively sensitive towards sulfur (Table 1), DLs for sulfur-containing pesticides were lower than with FPD,[43] and the linearity problems of the FPD were eliminated.[55] Some pesticides also contain nitrogen and oxygen, but GC/AED is relatively insensitive towards these elements owing to atmospheric contamination of the plasma. Nevertheless, pesticides have been detected by GC/AED in several environmental samples utilizing nitrogen-selective detection. The method was limited to pesticides present above the 1.5–25-ng level in the final extracts, and the GC/AED DLs were found to be a factor of 10^3–10^4 higher than for NPD.[54]

5.5 Chlorinated Biphenyls and Phenols

Among the large number of polyhalogenated organic micropollutants included in environmental monitoring

programs, most attention has been focused on the GC/AED determination of PCBs. These compounds, which were used as, for example, electrical insulators and flame retardants until the 1980s, have been detected by GC/AED in human blood,[56] seal blubber,[56] beef tallow,[57] fish oil,[57] fish liver,[58] and marine sediments.[16,58] In addition to PCBs, their methylsulfonyl metabolites have also been detected in seal blubber by GC/AED.[56] With GC/AED, excellent selectivity has been reported for PCBs in the chlorine-selective mode (Figure 2).[16] Thus, GC/AED has been successfully applied for the determination of PCBs in highly contaminated marine sediments, while the established techniques of electron capture and mass spectrometric detection suffered from matrix interferences.[16] Additionally, quantification was significantly simplified by GC/AED because responses were dependent solely on the moles of chlorine present[16,57,58] (see also Table 2). Thus, individual PCB congeners and total PCB were quantified with a single chlorine calibration curve (universal calibration). Unfortunately, with the first generation of the commercial GC/AED instrument, individual PCBs were not detected below the 250–400-pg level.[16,57,58] This was a factor of 10^4 higher than reported with ECD, and a factor of 10^2 higher than with electron ionization mass spectrometric detection in the selected ion monitoring mode. Therefore, extensive analyte preconcentration was required to obtain DLs at the 0.15-ppm level for individual PCB congeners in fat.[57] Minor technical modifications of the commercial GC/AED instrument have been found to improve PCB DLs by a factor of approximately 5,[56] but even these values are relatively high for PCB applications. Thus, while GC/AED may be utilized for contaminated samples, the technique is currently not an alternative for the monitoring of PCB background levels.

In addition to PCBs, some GC/AED interest has been focused on the determination of chlorophenols (CPs) which originate as industrial byproducts. With principal attention on water, GC/AED was found to provide excellent selectivity for CPs in the chlorine-selective mode, and CPs were determined in water below the 0.5-ppb level.[59,60]

5.6 Other Compounds Containing Nonmetallic Elements

Above, attention was focused on organic micropollutants containing metallic elements (Sn, Pb, Hg), pesticides, PCBs, and CPs. For all of these contaminants, substantial research has been documented within the literature utilizing the commercial GC/AED system, and GC/AED has been demonstrated to be an attractive alternative to existing methods. In addition to the above mentioned components, several other organic micropollutants have been detected by GC/AED, including polychlorinated dibenzodioxins (PCDDs), volatile organochlorines, trichloroacetic acid, chlorinated byproducts of humic and fulvic acids, chlorinated aromatics, polybrominated biphenyls (PBBs), polybrominated diphenylethers (PBDEs), iodated herbicides, volatile sulfur compounds, nitrosubstituted aromatics, and nitro musks. More information on these applications as well as others can be found in a review article concerned with environmental applications of GC/AED.[61]

6 CURRENT STATUS AND FUTURE DIRECTIONS

The literature reviewed in the present paper has demonstrated the great potential of GC/AED for analysis of organic micropollutants. Owing to the elemental capability, GC/AED enables rapid screening by elemental content of environmental samples, provides important structural information complementary to mass spectral data, and enables simplified quantitation based on universal calibration with a single elemental calibration curve. Particularly for environmental analysis, which frequently is complicated by matrix constituents, the very high elemental selectivity of GC/AED may reduce both interference and the demands of sample cleanup. However, as pointed out above, DLs of GC/AED are relatively high for some elements and extensive analyte preconcentration may be crucial. This, in combination with the lack of low-price commercially available instrumentation, currently limits the propagation of GC/AED in environmental laboratories.

For the future, therefore, it is hoped that the number of companies committed to producing GC/AED instrumentation will increase to reduce the price level of this highly versatile technology. With some further effort to improve DLs and to include the concept in standard procedures for the monitoring of organic micropollutants, GC/AED may rapidly become a ''work horse'' in laboratories concerned with environmental chemistry.

ABBREVIATIONS AND ACRONYMS

AED	Atomic Emission Detection
CP	Chlorophenol
DCP	Direct Current Plasma
DL	Detection Limit
ECD	Electron Capture Detection
ELCD	Electrolytic Conductivity Detection
FPD	Flame Photometric Detection
GC	Gas Chromatography

GC/ECD	Gas Chromatography/Electron Capture Detection
ICP	Inductively Coupled Plasma
MIP	Microwave Induced Plasma
MS	Mass Spectrometry
NPD	Nitrogen–Phosphorus Detection
O-FID	Oxygen-flame Ionization Detection
PBBs	Polybrominated Biphenyls
PBDEs	Polybrominated Diphenylethers
PCB	Polychlorinated Biphenyl
PCDD	Polychlorinated Dibenzodioxin
SCD	Sulfur Chemiluminescence Detection

The presence, identity and quantity of amines in the environment should be established to evaluate possible health hazards. In many cases, environmental amines are present at very low concentration and are often found among a myriad of other compounds from which they must be separated and identified. Therefore, analytical methodology for the isolation and quantification of these amines needs selective and sensitive detection. The present article is concerned with the utilization of selective gas chromatographic detectors for amine analysis and their application to the determination of amines in environmental samples.

1 INTRODUCTION

1.1 Hazardous Amines from Environmental Sources

As environmental issues and global environmental change are generating an increasing amount of attention worldwide, the occurrence and toxicity of hazardous chemicals in the biosphere have received a great deal of attention in recent years. As technology progressed and man's appetite for a carefree life expanded, the problems of environmental pollution became more complex and difficult to alleviate.[1] The three main categories of pollution are water pollution, air pollution and soil pollution, and knowledge of these types of pollution has become an urgent requirement for the protection of the terrestrial environment. The environment contains a variety of naturally occurring and anthropogenic pollutants to which humans are exposed. Moreover, every year many new substances are synthesized that differ radically from the natural products that exist in biosystems. Many of these compounds are not biodegradable and will thus progressively pollute the environment. Among the many environmental pollutants, the occurrence and determination of amines have recently received a great deal of attention. These amines occur in a number of ambient environments such as air, water, soil and foods, and have become a source of serious social and hygienic problems.[2,3]

Aliphatic and aromatic mono-, di- and polyamines are naturally occurring compounds formed as metabolic products in microorganisms, plants and animals, in which the principal routes of amine formation include the decarboxylation of amino acids, amination of carbonyl compounds and degradation of nitrogen-containing compounds. These amines are considered to play a significant role as storage sources of nitrogen and precursors for the synthesis of hormones, alkaloids, nucleic acids and proteins. Amines are also widely used as raw materials or at an intermediate stage in the manufacture of industrial chemicals.[2–6] In particular, aromatic amines such as aniline and its substituted analogs, phenylenediamine and diphenylamine, have been widely used as industrial intermediates[2,7–9] in the manufacture of carbamate and urethane pesticides, dyestuffs, cosmetics and medicines. These amines have also been employed in the rubber industry as antioxidants and antiozonants[5] and as components in epoxy and polyurethane polymers.[4,10] An additional source for amines in the environment is the abiotic and biotic degradation of animal waste, domestic waste and industrial products.[9,11,12] Many of these amines have been discharged into the atmosphere[10,13–30] and water[18,31–48] from anthropogenic sources such as cattle feedlots and near livestock buildings,[13] waste

incineration, sewage treatment, automobile exhaust, cigarette smoke,[11,25,49–54] soil,[22,23,38,41,55] foods [56–61] and various industries.[2,3,6,7,62] These amines have also been detected in biological samples.[12,35,63–66] Many amines have an unpleasant smell and are hazardous to health, i.e. as sensitizers and irritants to the skin, eye, mucous membrane and respiratory tract.[67] Some amines are also suspected to be allergenic and mutagenic or carcinogenic substances owing to their adsorption tendency in tissues.[68,69] In particular, the toxicity of aromatic amines to mammals and fish is well established,[69,70] and many of these amines are known to be highly mutagenic and carcinogenic and to form adducts with proteins and DNA.[7,68,71–79] Several polycyclic aromatic amines such as benzidine, 4-aminobiphenyl and 2-naphthylamine have been also classified by the International Agency for Research on Cancer (IARC) as known human carcinogens.

Aliphatic and aromatic amines not only are toxic in themselves but also become toxic *N*-nitrosamines through chemical reactions with nitrosating agents such as nitrite or nitrate.[80–83] In general, the nitrosation of amines occurs in the human diet, the environment and in vivo in the stomach or small intestine of experimental animals.[84–87] The reaction of nitrosating agents with primary amines produces short-lived alkylating species that react with other compounds in the matrix to generate products (mainly alcohols) devoid of toxic activity in the relevant concentrations. The nitrosation of secondary amines leads to the formation of stable *N*-nitrosamines whereas that of tertiary amines produces a range of labile *N*-nitroso products. Although the reaction pathways are uncertain, it has also been demonstrated in model experiments that amines react with NO_x and OH radicals in air to form nitrosamines and nitramines.[62,88] Moreover, it is considered that volatile *N*-nitrosamines in cigarette smoke are formed from the decarboxylation of *N*-nitrosoamino acids, pyrolytic nitrosation of secondary amines and concentrated decarboxylation/nitrosation of amino acids during combustion processes.[82] *N*-Nitrosamines are widely distributed in foodstuffs[61,81,89–93] and various human environments such as indoor and outdoor air,[85,94,95] combustion smoke,[52,82,96–103] water,[104–108] sediment,[109] household dishwashing liquids,[110] foods,[81,89,91–93,111] rubber products,[111–119] metalworking fluids,[120] drug formulations[121,122] and agricultural chemical formulations.[110,123,124] Furthermore, some *N*-nitrosamines have been detected in human gastric juice, saliva and cervical mucus.[125,126] *N*-Nitrosamines represent a major class of important chemical mutagens, carcinogens, teratogens and immunotoxic agents, which have been described as a serious hazard to human health.[68,127–130] Recent developments in environmental carcinogenesis have demonstrated that *N*-nitrosamines lead to a wide variety of tumors in many animals, which are likely to result in the formation of DNA adducts.[68,78,131,132] The toxicity of *N*-nitrosamines can be manifested even at the micrograms per kilogram level.

A new series of heterocyclic amines formed during heating of amino acids, proteins, creatinine and sugars are potent mutagens in the Ames/*Salmonella* assay.[133–140] Many of these mutagenic heterocyclic amines have been isolated and identified not only from various proteinaceous foods [141–155] including cooked meats and fish, but also from environmental components such as airborne particles and diesel-exhaust particles,[156,157] combustion smoke[158–164] indoor air,[165–167] cooking fumes,[168–170] rainwater[165,166,171] and river water.[172] Moreover, some mutagenic heterocyclic amines have been detected in biological samples such as urine, plasma, bile and feces.[150,173–176] These facts suggest that heterocyclic amines may be emitted into the atmosphere through combustion of various materials such as foods, wood, grass, garbage and petroleum, and discharged into the water through domestic waste and human waste, although their mechanisms have not been determined. Some heterocyclic amines have much higher mutagenic activity than typical mutagens/carcinogens such as aflatoxin B1, AF-2 and benzo[*a*]pyrene and have been verified to be carcinogenic in rats and mice.[133–137,139,177,178] These compounds induced tumors in the liver, small and large intestine, Zymbal gland, clitoral gland, skin, oral cavity and mammary gland in rats, and the liver, forestomach, lung, hematopoietic system, lymphoid tissue and blood vessels in mice. 2-Amino-3-methylimidazo[4,5-*f*]quinoline (IQ) was also found to be carcinogenic in the monkey, inducing hepatocellular carcinomas.[179,180] Moreover, recent investigations revealed that heterocyclic amines also possess cardiotoxic effects[178] and various pharmacotoxicological activities such as convulsant activity[181,182] and potent inhibitory effects on platelet function and dopamine metabolism. [182–186] However, significant risks to human health and the environment through long-term exposure and bioaccumulation of heterocyclic amines are scientifically unclear.

1.2 Objective and Scope

The presence, identity and quantity of amines in the environment should be established to evaluate possible health hazards. In many cases, environmental amines are present at very low concentration and are often found among a myriad of other compounds from which they must be separated and identified. Therefore, analytical methodology for the isolation and quantification of these amines needs selective and sensitive detection. The present article is concerned with the utilization of the

selective gas chromatography (GC) detectors for amine analysis and their application for the determination of amines in environmental samples. The article consists of two parts. In the first part (section 2), general aspects of the selective detection of amines by GC are surveyed according to the detector types. In the second part (section 3), the applications of selective GC methods in environmental analysis are considered according to the amine types. The article covers not only aliphatic and aromatic primary, secondary and tertiary amines but also *N*-nitrosamines and heterocyclic amines that often occur in various environments as highly toxic compounds. References that have appeared in the past two decades are cited. General aspects of GC detectors have been reviewed in several books.[187–190] General aspects of environmental analysis by GC have also been detailed in several books[190–192] and reviews.[2,3]

2 SELECTIVE DETECTORS FOR ANALYSIS OF AMINES BY GAS CHROMATOGRAPHY

2.1 Amine Analysis by Gas Chromatography

GC has been widely used for amine analysis because of its inherent advantages of simplicity, high resolving power, high sensitivity, short analysis time and low cost. However, GC analysis of free amines generally has some inherent problems related to the difficulty in handling low-molecular-mass amines because of their high water solubility and high volatility. Therefore, these amines are difficult to extract from water and are not easily chromatographed owing to their polarity. Furthermore, amines are tend to be adsorbed and decomposed on the columns, and readily give tailed elution peaks, ghosting phenomena and low detector sensitivity. The adsorption tendency in the analytical systems, i.e. in sample vessels, injection system, glass wool and GC column, decreases in the order primary > secondary > tertiary amines, and it is generally more difficult to chromatograph aliphatic than aromatic amines. A common method of overcoming these problems is to convert such polar compounds into relatively nonpolar derivatives more suitable for GC analysis. Derivatization methods have been employed to reduce the polarity of the amino group and improve GC properties. Derivatization reactions, often selective for amine type (primary, secondary, tertiary), have also been used to improve the detection and separation of these amines. A number of derivatives such as acyl, silyl, dinitrophenyl, permethyl, Schiff base, carbamate, sulfonamide and phosphonamide compounds have been used for this purpose. For example, introducing halogen- and phosphorus-containing groups in the molecule enhances the response of the electron-capture detector (ECD) and flame photometric detector (FPD), respectively. These derivatization reactions were described in detail in previous review.[3] For amine analysis, a wide variety of detectors such as the thermionic detector, FPD, ECD, electrolytic conductivity detector (ELCD) and chemiluminescent detector (CLD) can be used, and offer increased selectivity for specific amines. Furthermore, the combined technique of gas chromatography/mass spectrometry (GC/MS) can provide structure information for the unequivocal identification of amines and these amines can be determined with mass-selective detector (MSD) based on a selected-ion monitoring (SIM). By using these detectors, subnanogram detection limits can be achieved. GC detectors for environmental amine analysis are summarized in Table 1. Although most detectors respond directly to amines, some detectors, such as the FPD and ECD, need conversion of amines into suitable derivatives prior to detection.

2.2 Thermionic Detector

The thermionic detector, which evolved from the flame ionization detector (FID), is particularly suitable for the analysis of compounds containing nitrogen and phosphorus. There are two types of thermionic detectors depending on whether a flame is present in or absent in the detector system. In general, a flame-type thermionic detector is called a flame thermionic detector (FTD) or alkali flame ionization detector (AFID), and a flameless-type detector is called a thermionic specific detector (TSD) or nitrogen–phosphorus detector (NPD). The flame type can also detect halogen-containing compounds, but the flameless type selectively respond only to N- and P-containing compounds. A diagram of a Hewlett-Packard NPD is shown in Figure 1.

Although the mechanism of the response of the thermionic detector for N- and P-containing compounds is not fully understood, a widely accepted explanation is as follows. The normal FID ion collection assembly is replaced with a collector that has a small alumina cylinder coated with a rubidium salt (active element), which is heated electrically, creating a thermionic source. In this environment, N- and P-containing organic compounds are ionized. The detector collects the ions and measures the resulting current with an electrometer. The flame in the NPD is not ignited, but rather is adjusted to give a low-temperature plasma. This plasma is not used to heat the collector, but only for ion production and dissociation as the organic compounds eluted from the column. For N-containing compounds, pyrolysis takes place, producing intermediate stable CN radicals and then the radicals formed take electrons from the excited atom of the alkali

Table 1 Selective GC detectors for environmental amine analysis

GC detector	Amines	Matrix	References
Thermionic detector	Aliphatic amines	Air	Kuwata et al.[13]
	Aliphatic and aromatic amines	Working atmosphere	Audunsson and Mathiasson,[14,15] Skarping et al.[16]

	N-Nitrosamines	Drug formulation	Dawson and Lawrence,[121] Nielsen and Lings[122]
GC/MS	Aliphatic tertiary amine	Airborne	Seeber et al.[11]
	Aliphatic amines	River water, sediment, wastewater	Koga et al.,[36] Avery and Junk,[37] Terashi et al.,[38] Pietsch et al.,[39] Sacher et al.[40]
	Aliphatic tertiary amines	Lake water, sediment	Tsukioka et al.[41]
	Aromatic amines	Airborne	Meichini et al.[24]
	Aromatic amines	Combustion smoke, indoor air	Pieraccini et al.[25,53]
	Aromatic amines	Groundwater, river water, sediment	Okumura et al.,[45] Longo and Cavallaro,[46] Muller et al.[47,48]
	N-Nitrosamines	Cigarette smoke	Arrendale et al.[103]
	N-Nitrosodimethylamine	Drinking water	Sen et al.[105]
	N-Nitrosamines	Herbicides	Frassanito et al.[124]
	Heterocyclic amines	Cooking fumes	Vainiotalo et al.[168]

metal, resulting in a cyanide ion. A positive alkali metal ion migrates to the collector electrode and again liberates an electron. Therefore, compounds not containing a C–N bond, such as nitrogen gas, nitrogen oxides and ammonia, cannot respond to the NPD.

Thermionic detectors require hydrogen and air as with the FID, but at lower flow rates. Therefore, normal FID-type ionizations are minimal, and the selectivity ratios for detection of N- and P-containing compounds versus carbon detection are $3.5 \times 10^4 : 1$ and $7.5 \times 10^4 : 1$,

respectively. The sensitivity of a thermionic detector is about 0.4–10 pg for N-containing compounds and 0.1–1 pg for P-containing compounds, and it is about 50–500 times more sensitive for nitrogen and phosphorus, respectively, than the FID. The main disadvantage of this detector is that its performance deteriorates with time. The alkali metal salt employed as the bead is continuously lost during the operation of the detector. Furthermore, the thermionic detector is not usable with columns of liquid phases containing halogen, phosphorus or nitrogen such as XE-60 and OV-210. In addition, the use of column, supports, glass wool treated with phosphoric acid and leak-detection fluids should be avoided to preserve the lifetime of the active element.

Figure 2 Gas chromatograms obtained from standard C_1–C_4 aliphatic amines and polluted sources. (a) Standard amines, 6 ng; (b) air in a cowshed; (c) air around a fermentation system of poultry wastes. GC conditions: column, alkalinized GHP-1 (2 m × 2 mm i.d.); column temperature, isothermal at 140 °C for 3 min and then programmed from 140 to 170 °C at 10 °C min^{-1} and isothermal at 170 °C for 10 min; injection temperature, 180 °C; detector temperature, 250 °C; carrier gas, nitrogen at 45 mL min^{-1}. Peaks: 1 = methylamine; 2 = dimethylamine; 3 = ethylamine; 4 = trimethylamine; 5 = isopropylamine; 6 = *n*-propylamine; 7 = *tert*-butylamine; 8 = diethylamine; 9 = *sec*-butylamine; 10 = isobutylamine; 11 = *n*-butylamine. (Reprinted by permission from K. Kuwata, E. Akiyama, Y. Yamazaki, H. Yamasaki, Y. Kuge, Y. Kiso, *Anal. Chem.*, **55**, 2199–2201 (1983), Copyright 1983, American Chemical Society.)

The thermionic detector is one of the most popular selective detectors for the GC analysis of amines and is used for the analyses of various amines such as aliphatic[13–18,56,63,193–196] and aromatic[19,26,55,56,193,197] amines, *N*-nitrosamines[89,123] and heterocyclic amines.[20,158,198] Kuwata et al.[13] reported that 11 low-molecular-mass aliphatic amines could be determined at the parts per billion level by flame-type thermionic detector (Figure 2a). Aliphatic amines were also detected with TSD after acylation,[16,194] permethylation[195] and isobutoxycarbonylation.[196] Skarping et al.[26,64,194,197] reported that some aliphatic and aromatic amines can be detected at the femtomole level with a TSD. Kataoka et al.[50] separated 22 aromatic amines using an HP-5 capillary column within 15 min (Figure 3a). This method is based on derivatization with *n*-propyl chloroformate and subsequent NPD analysis, and can detect picogram levels of aromatic amines. Furthermore, Kataoka and Kijima[198] developed a simple and rapid derivatization method for the GC analysis of heterocyclic amines. Ten heterocyclic amines were determined as their *N*-dimethylaminomethylene derivatives with an NPD. The detection limits of these compounds ranged from 2 to 15 pg.

2.3 Flame Photometric Detector

The FPD, based on a chemiluminescent species produced during the burning process in a hydrogen-rich flame, is a selective detector for compounds containing sulfur and phosphorus. The emission of S-containing compounds ranges from 390 to 480 nm and that of P-containing compounds from 480 to 580 nm. By choosing a filter having a transmission window of wavelength 390–410 nm for S-containing compounds or 520–560 nm for P-containing compounds, the maximum emission from S- or P-containing compounds can be sensed by the photomultiplier. The emission of hydrocarbons is between 390 and 520 nm, and therefore the emission from the background hydrocarbons will be almost negligible.

A diagram of a Hewlett-Packard FPD is shown in Figure 4. The detector is essentially an FID equipped with a filter that can be changed according to the desired wavelength for sulfur or phosphorus. The end of the capillary column is led into the flame jet where the column eluate mixes with hydrogen flow and is burned. The light emitted passes through two heat filters and then through the selective filter and finally on to the photomultiplier. The chemical reactions that occur in the flame and emission zone are complex depending on the gas flows and temperature. Sulfur and phosphorus are detected as S=S and HPO molecules, respectively. These molecules are created in a metastable state and, when they decay, they release energy in the form of a photon of a specific wavelength. The light emitted from S-containing compounds is not linear

Figure 3 Gas chromatograms obtained from *n*-propoxycarbonyl derivatives of aromatic amines and cigarette smoke sample. (a) Standard amine derivatives (each peak corresponding to 1–5 ng of amine); (b) cigarette smoke sample. GC conditions: column, HP-5 (30 m × 0.32 mm i.d.); column temperature, programmed from 120 to 220 °C at 10 °C min^{-1} and then from 220 to 320 °C at 20 °C min^{-1} and isothermal at 320 °C for 1 min; injection and detector temperatures, 330 °C; carrier gas, helium, programmed from 80 to 120 kPa at 4 kPa min^{-1} and then from 120 to 270 kPa at 30 kPa min^{-1} and held at 270 kPa for 1 min; detector, NPD. Peaks: 1 = aniline; 2 = internal standard (*N*-methyl-*m*-toluidine); 3 = 2-toluidine; 4 = 2, 6-xylidine; 5 = 3-toluidine; 6 = 4-toluidine; 7 = 2-ethylaniline; 8 = 2,5-xylidine; 9 = 2,4-xylidine; 10 = 2,3-xylidine; 11 = 3,5-xylidine; 12 = 4-ethylaniline; 13 = 3,4-xylidine; 14 = α-naphthylamine; 15 = *o*-aminobiphenyl; 16 = *N*-phenylnaphthylamine; 17 = internal standard (2,4-diaminotoluene); 18 = 2-aminofluorene; 19 = *p*-aminoazobenzene; 20 = benzidine; 21 = *p*,*p*′-diaminodiphenylmethane; 22 = 2-aminoanthracene.

Figure 4 Diagram of a FPD optimized for use with capillary columns. (Reproduced by permission of Hewlett-Packard from K.J. Hyver, P. Sandra, *High Resolution Gas Chromatography*, 3rd edition, Hewlett-Packard, Avondale, PA, Chapters 4–20, 1989.)

with concentration owing to the reactions in the flame, but is approximately proportional to the square of the sulfur atom concentration. The selectivity ratio for detection of S- or P-containing compounds versus carbon detection is $10^4:1$. The sensitivity of the FPD is about 20 pg for S-containing compounds and 1 pg for P-containing compounds. One serious problem with the FPD is the quenching or reabsorption of the light emitted by the selected species. Hydrocarbon quenching occurs from collisions when the peak of S-containing compounds is co-eluted with another hydrocarbon in relatively high concentration. Self-quenching, which is due to collisional energy absorption, competing chemical reactions or the reabsorption of the photon by an inactivated species, can also occur at high concentrations of the heteroatom species. Precise control of the gas flow to the detector virtually eliminates quenching of the detector response.

Although the FPD is widely used for S- and P-containing compounds such as agricultural chemicals and SO_2 in the environment, it can also detect amino compounds by conversion into their S- or P-containing derivatives.[51,52,57,58,65,96,199,200] Hamano et al.[57] and Kataoka et al.[65,199] reported that primary and secondary aliphatic amines could be detected as their *N*-benzenesulfonyl derivatives by FPD in the S mode. As shown in Figure 5(a) and (b), 14 primary and 9 secondary amines were separately determined. The detection limits of these amines ranged from 10 to 100 pg. Furthermore, Kataoka et al. reported that aliphatic[58,200] and aromatic[51] amines and *N*-nitrosamines[52,96] could be analyzed as their *N*-dialkylthiophosphoryl derivatives with an FPD in the P mode. In particular, secondary amines can be selectively converted into their *N*-diethylthiophosphoryl derivatives after treatment with *o*-phthaldialdehyde (OPA), because OPA reacts only with primary amino groups. As shown in Figure 6(a–d), primary amines are also derivatized without OPA treatment and detected with an FPD, but they are not detected at all with OPA pretreatment. On the other hand, secondary amines are detected irrespective of OPA pretreatment, because these amines do not react with OPA. This technique is also applied to the determination of *N*-nitrosamines, which are denitrosated with hydrobromic acid to produce the corresponding secondary amines and then derivatized.

2.4 Electron-capture Detector

The ECD, which consists of a radioactive source such as ^{63}Ni, is selective detector for halogenated or nitrated compounds, organometallics and conjugated carbonyls. Electron-capture detection involves the following three steps: generation of thermal energy electrons, capture of some of these electrons by an electrophilic compound and collection and measurement of the unreacted electrons. In order to produce capturable (low-energy) thermal electrons, the carrier gas is ionized by β-particles from a radioactive source placed in the cell. This electron flow produces a small current, which is collected and measured by a suitable amplifier. When the sample molecule is introduced into the cell, electrons are captured by the sample, resulting in a decreased current. The detector can be used in two ways: either with a constant potential applied across the cell (dc mode) or with a pulse potential across the cell (pulse mode). In the dc mode, hydrogen or nitrogen can be used as the carrier gas and a small potential (a few volts) is applied across the cell just sufficient to collect all the electrons available and provide a small standing current. When an electron-capturing molecule enters the cell, the electrons are captured by the molecule and the molecules become charged. The mobility of the captured electrons is much reduced compared with the free electrons and therefore the electrode current falls dramatically. On the other hand, in the pulse mode, a mixture of 10% methane in argon is usually used as the carrier gas and the electron-capturing environment is different. The period of the pulsed potential is adjusted such that relatively few of the slow negatively charged molecules reach the anode, but the faster moving electrons are all collected. A diagram of a Hewlett-Packard ECD is shown in Figure 7. The anode and cavity are in a ''pi and cup'' geometry, and the radioactive source is ^{63}Ni plated on the cup. Although the selectivity

Figure 5 Gas chromatograms obtained from benzenesulfonyl derivatives of (a) primary and (b) secondary amines. GC conditions: column, DB-1 (15 m × 0.53 mm i.d.); column temperature, programmed from 120 to 280 °C at 10 °C min^{-1}; injection and detector temperatures, 290 °C; nitrogen flow-rate, 10 mL min^{-1}; detector, FPD (S mode). Each peak corresponds to 2 ng of amine. Peaks: 1 = methylamine; 2 = ethylamine; 3 = isopropylamine; 4 = *n*-propylamine; 5 = isobutylamine; 6 = *n*-butylamine; 7 = isoamylamine; 8 = *n*-amylamine; 9 = hexylamine; 10 = cyclohexylamine; 11 = heptylamine; 12 = benzylamine; 13 = octylamine; 14 = β-phenylethylamine; 15 = dimethylamine; 16 = diethylamine; 17 = dipropylamine; 18 = pyrrolidine; 19 = morpholine; 20 = piperidine; 21 = dibutylamine; 22 = hexamethyleneimine; 23 = *N*-methylbenzylamine. (Reprinted from H. Kataoka, *J. Chromatogr. A*, **733**, 19–34 (1996), Copyright 1996, with permission from Elsevier Science.)

depends on the affinity of compounds for the electrode, the selectivity ratio for detection of polyhalogenated compounds versus carbon detection is 10^5–10^6 : 1. The ECD is extremely sensitive, probably the most sensitive GC detector available. Although the sensitivity of the ECD depends on the molecular structure, that of chlorinated compounds is about 0.05–1 pg. For successful electron-capture detection, it is important that carrier and purge gases are very clean and dry (99.9995%).

Although the ECD is widely used in the detection and analysis of halogenated compounds, in particular pesticides, it can also detect amino compounds by conversion into halogen-containing derivatives.[32–34,120,194,201–205] Miyamoto et al.[201] determined selectively some primary amines as their *N*-benzenesulfonyl-*N*-trifluoroacetyl derivatives by gas chromatography/electron-capture detector (GC/ECD). Skarping et al.[204] reported that aromatic amines could be separated as their perfluoro fatty acid

Figure 6 Gas chromatograms obtained from *N*-diethylthiophosphoryl derivatives of primary and secondary amines. (a) Primary amines; (b) primary amines pretreated with OPA; (c) secondary amines; (d) secondary amines pretreated with OPA. GC conditions: column, DB-1701 (15 m × 0.53 mm i.d.); column temperature, programmed from 100 to 260 °C at 10 °C min^{-1}; injection and detector temperatures, 280 °C; nitrogen flow-rate, 10 mL min^{-1}; detector, FPD (P mode). Each peak corresponds to 20 pmol of amine. Peaks: 1 = methylamine; 2 = ethylamine; 3 = *n*-propylamine; 4 = isobutylamine; 5 = *n*−butylamine; 6 = isoamylamine; 7 = *n*-amylamine; 8 = hexylamine; 9 = cyclohexylamine; 10 = heptylamine; 11 = benzylamine; 12 = octylamine; 13 = β-phenylethylamine; 14 = dimethylamine; 15 = diethylamine; 16 = dipropylamine; 17 = pyrrolidine; 18 = piperidine; 19 = morpholine; 20 = dibutylamine; 21 = hexamethyleneimine; 22 = *N*-methylcyclohexylamine; 23 = *N*-methylbenzylamine. amides with a glass capillary column and determined using on-column injection and ECD (Figure 8a and b). The detection limits of these amines were ca. 1 pg. Furthermore, Schmidt et al.[33,34] reported a selective and sensitive method for the determination of aromatic amines based on derivatization to the corresponding iodobenzenes and subsequent GC/ECD analysis. Separation of at least 30 compounds in a single chromatographic run in 30 min is possible (Figure 9) and 56 aromatic amines were investigated. On the other hand, dinitroaniline herbicides could be directly analyzed by GC/ECD, because they possess a nitro group in the molecule.[35]

2.5 Chemiluminescence Detector

The CLD or thermal energy analyzer (TEA), based on emission spectroscopy, is a selective detector for nitroso and nitroaromatic compounds. The response of the TEA to *N*-nitroso compounds is based on the reaction of nitrogen oxide with ozone combined with the preceding pyrolysis of nitroso compounds. A schematic diagram of a TEA is shown in Figure 10. The eluate from the GC column enters the pyrolyzer where the selective catalytic decomposition of *N*-nitroso compounds takes place, resulting in a nitrosyl radical and an organic radical. The N−NO bond is the weakest in these compounds. The pyrolyzer eluent expands into the evacuated reaction chamber in which the nitrogen oxide reacts with ozone, resulting in excited nitrogen dioxide. The excited nitrogen dioxide rapidly decays back to its ground state with the characteristic emission of light. Then the emitted radiation is detected by a photomultiplier through a red optical filter. The filter is used to block possible light emission resulting from sources other than NO chemiluminescence. The intensity of the emission is proportional to the nitrosyl radical concentration, and hence to the *N*-nitroso compound concentration. The decomposition of substances with a catalyst at lower temperatures of

Figure 7 Diagram of an ECD design showing the capillary column interface. (Reproduced by permission of Hewlett-Packard from K.J. Hyver, P. Sandra, *High Resolution Gas Chromatography*, 3rd edition, Hewlett-Packard, Avondale, PA, Chapters 4–18, 1989.)

about 300 °C is more advantageous than pyrolysis at elevated temperatures, because the decomposition of the N–NO bond is more selective, even though the detector response to nitrosamines is diminished at lower temperature. The response of the CLD to nitroaromatic compounds increases rapidly with increasing temperature at 800–900 °C of the pyrolyzer. Nitrogen-containing compounds are also detected with CLD, based on the catalytic decomposition of these compounds in the presence of oxygen at temperatures of 900–1000 °C and on the subsequent ozone oxidation of the nitrogen oxide formed, as with nitroso compounds. The sensitivity of CLD for *N*-nitrosodimethylamine is about 50 pg.

The CLD has been used as a selective detector for *N*-nitrosamines.[94,95,97–118,121,122] Fadlallah et al.[95] separated volatile *N*-nitrosamines within 12 min (Figure 11a). Adams et al.[98] analyzed tobacco-specific *N*-nitrosamines by GC/TEA. The CLD can be used for the selective analysis of not only *N*-nitrosamines but also aliphatic[21–23,59] and aromatic[202] amines by modification of the pyrolyzer temperature. Pfundstein et al.[59] reported that primary and secondary amines could be analyzed as their *N*-benzenesulfonyl derivatives by gas chromatography/chemiluminescent detection (GC/CLD) with a modified TEA. Thermal pyrolysis of amines at 720 °C with a nickel catalyst is used to produce NO radicals.

Figure 8 Chromatograms of amine derivatives. (a) pentafluoropropionic acid (PFPA) derivatives; (b) heptafluorobutyric anhydride (HFBA) derivatives. GC conditions: column, OV-73 (25 m × 0.32 mm i.d.); on-column injection of 2 µL of toluene solution at 115 °C; column temperature, isothermal at 115 °C for 2 min and then programmed from 115 to 300 °C at 10 °C min^{-1} and held at 300 °C for 5 min; carrier gas, helium at 0.8 kg cm^{-2}; detector, ECD (constant-current mode); make-up gas, argon–methane (95 : 5) at 55 mL min^{-1}. Each peak corresponding to 20–80 pg of amine. Peaks: 1 = aniline; 2 = 2,6-toluidine; 3 = 2,4-toluidine; 4 = 2,4-diaminoanisole; 5 = α-naphthylamine; 6 = β-naphthylamine; 7 = 4-aminobiphenyl; 8 = 1,5-naphthalenediamine; 9 = benzidine; 10 = 4,4′-methylenedianiline; 11 = *o*-tolidine; 12 = 4,4′-methylenebis-(*o*-chloroaniline); 13 = 4,4′-diamino-3,3′-dimethoxybiphenyl(*o*-dianisidine). Peaks denoted R refer to reagent and solvent impurities. (Reprinted from G. Skarping, L. Renman, B.E.F. Smith, *J. Chromatogr.*, **267**, 315–327 (1983), Copyright 1983, with permission from Elsevier Science.)

2.6 Mass-selective Detector

MSD has been recognized as an excellent detector for GC, because the spectral data provide the qualitative information lacking in other GC detectors. When a molecule in the vapor state is bombarded with electrons,

Figure 9 GC separation of 33 iodinated derivatives of aromatic amines after enrichment on HR-P phase. Concentration of aromatic amines, 10–50 ng mL^{-1}. GC conditions: column, 5% phenylmethylpolysiloxane (30 m × 0.25 mm i.d.); column temperature, isothermal at 135 °C for 20.5 min, then programmed from 135 to 235 °C at 12.5 °C min^{-1} and held at 235 °C for 8.5 min; injection and detector temperatures, 250 and 300 °C, respectively; carrier gas, nitrogen at 100 kPa; split ratio, 1:120; detector, ECD. Peaks: 1 = 4-aminotoluene; 4 = 2,4-diaminotoluene; 5 = 4-amino-2-nitrotoluene; 6 = 2,6-diaminotoluene; 7 = 2-amino-6-nitrotoluene; 8 = 2,6-diamino-4-nitrotoluene; 9 = 2-amino-4-nitrotoluene; 10 = 4-amino-2,6-dinitrotoluene; 11 = 2,4-diamino-6-nitrotoluene; 12 = 2-amino-4,6-dinitrotoluene; 13 = aniline; 14 = 1,3-phenylenediamine; 17 = 3-nitroaniline; 18 = 4-nitroaniline; 24 = 2-amino-3-nitrotoluene; 25 = 2-amino-5-nitrotoluene; 29 = 2,6-dimethylaniline; 30 = 3,4-dimethylaniline; 31 = 3,5-dimethylaniline; 33 = 1-naphthylamine; 34 = 2-naphthylamine; 35 = 2-aminobiphenyl; 36 = 4-aminobiphenyl; 37 = 4-isopropylaniline; 38 = 2,6-diethylaniline; 39 = 2-ethyl-6-methylaniline; 40 = 4-chloro*N*-methylaniline; 44 = 3,4-dichloroaniline; 46 = 4-chloro-2-methylaniline; 47 = 3-chloro-4-methoxyaniline; 50 = 2,6-dinitroaniline; 51 = 3,5-dinitroaniline; 52 = benzidine. (Reprinted from T.C. Schmidt, M. Less, R. Haas, E. von Low, K. Steinbach, G. Stork, *J. Chromatogr. A*, **810**, 161–172 (1998), Copyright 1998, with permission from Elsevier Science.)

bonds are ruptured and the molecle ionizes. The kind and amount of fragments obtained are characteristic of the molecule. In a magnetic sector MSD, when the positively charged fragments are accelerated into a magnetic field, they travel curved paths, the radii of which are proportional to the square roots of the masses of the ions. By varying the magnetic field, the segregated ion beams containing ions of identical mass-to-charge ratio are swept successively past a collector. Here the ions discharged, producing currents proportional to the relative abundances of ions of each mass. These currents are recorded successively to give the mass spectrum. On the other hand, a quadrupole MSD performs a different mass separation, using four rods with an electric field between them. As the ions enter the field, they interact with it in such a way that only ions of a specific mass-to-charge ratio will pass through to the detector. A scan of many ions is achieved by varying the electric field. An ion trap mass detector (ITD) can store the ions of a certain mass in stable paths for many seconds. The ion trap is scanned over a mass range whereby the ions are detected by a conventional electron multiplier. The two most common techniques used to produce ions in an MS are electron impact ionization (EI) and chemical ionization (CI). A schematic diagram of a typical electron impact ionization mass spectrometry (EIMS) system is shown in Figure 12.

An MSD consists of four main parts: ion source, mass analyzer, detector and instrument control and data-handling computer system. The first step in a GC/MS analysis is qualitative identification, using a complete scan across the entire mass range. Identification can be done with the help of spectral libraries, usually kept in a database on a computer with the detector-controlling software. The molecular ion and characteristic ions are used for the identification of compounds. The second step is quantitative analysis using SIM. By using a filter to select only a few ions, the sensitivity can be increased. The final step is the total ion chromatogram (TIC), based on the plot of total response (sum of all ions) over time by scanning repeatedly. For quantitative SIM analysis, it is necessary first to accomplish the optimum chromatography, select ions which are compound specific (molecular ion or fragment ion), give a large signal and have no interferences. Next it is necessary to

Figure 12 Schematic diagram of a typical mass spectrometer with an electron-impact ion source.

optimize the MSD response to the monitored ions, calibrate each ion mass and assign the dwell time for each ion using GC peak width and ion signal ratios.

GC/MS can provide structural information for the unequivocal identification of amines and can be applied to the analyses of various amines such as aliphatic [36–41] and aromatic[8,11,12–25,45–48,59,205] amines, *N*-nitrosamines[103,124–126] and heterocyclic amines.[141–145,168] Aliphatic amines are analyzed after derivatization with 2,4-dinitrofluorobenzene, benzenesulfonyl chloride and pentafluorobenzaldehyde (PFBA). Sacher et al.[40] reported that aliphatic primary and secondary amines could be determined as their *N*-benzenesulfonyl and 2,4-dinitrophenyl derivatives (Figure 13a and b) and the method using the former derivatives was more selective and sensitive. Longo and Cavallaro[46] developed a method for the simultaneous identification of 73 primary and secondary aromatic amines as their heptafluorobutyramides. (Figure 14) The electrophoretic derivatives were analyzed by GC combined with an ECNICI MSD. Detection limits of these amines were in the range 0.3–66.3 pg injected in the full-scan mode and 0.01–0.57 pg injected in the SIM mode. Furthermore, Skog et al.[145] analyzed six nonpolar heterocyclic amines by GC/MS in the SIM mode. Murray et al.[141–143] developed a sensitive and selective method for the determination of several heterocyclic amines as their 3,5-bistrifluoromethylbenzyl derivatives by negative-ion chemical ionization mass spectrometry (NICIMS) in the SIM mode. The detection limits were 1 pg.

Figure 13 Gas chromatograms of aliphatic primary and secondary amines. (a) Benzenesulfonyl derivatives; (b) 2,4-dinitrophenyl derivatives. GC conditions: DB-5 (35 m × 0.25 mm i.d.); (a) column temperature, isothermal at 120 °C for 3 min, then programmed from 120 to 220 °C at 5 °C min^{-1}, from 220 to 290 °C at 10 °C min^{-1} and held at 290 °C for 5 min; (b) column temperature, isothermal at 140 °C for 3 min, then programmed from 140 to 210 °C at 3 °C min^{-1}, from 210 to 290 °C at 10 °C min^{-1} and held at 290 °C for 5 min; injector and detector temperatures, 290 °C; carrier gas, helium at 1 mL min^{-1}; detector, MSD. Peaks: 1 = dimethylamine; 2 = methylamine; 3 = ethylamine; 4 = diethylamine; 5 = *n*-propylamine; 6 = *n*-butylamine; 7 = pyrrolidine; 8 = morpholine; 9 = piperidine; 10 = *n*-hexylamine internal standard; 11 = ethanolamine. Concentrations, 25 ng mL^{-1} each. (Reprinted from F. Sacher, S. Lenz, H.-J. Brauch, *J. Chromatogr., A*, **764**, 85–93 (1997), Copyright 1997, with permission from Elsevier Science.)

2.7 Electrolytic Conductivity Detector

The ELCD is a useful detector in environmental analysis owing to its selectivity for halogen-, sulfur- and nitrogen-containing compounds. This is done by mixing the effluent with a reaction gas (oxidizing or reducing) in a reaction catalyst (usually nickel). The resulting gas-phase reaction products are then combined with a stream of deionized solvent, producing a conductive solution. The electrical conductivity of the liquid is measured and recorded. In the case of nitrogen-mode analysis, the column eluate is reduced with H_2 at 800–900 °C in a nickel reaction tube, producing ammonia by the decomposition of organic nitrogen compounds. Under these conditions, the organic halogen, sulfur, oxygen and phosphorus compounds are converted into HX, H_2S, H_2O, PH_3 and lower alkanes. Although H_2S and lower alkanes (mainly methane) give a low response owing to the low ionization, the acidic products can be removed with a basic scrubber placed between the reaction chamber and the conductivity cell.

Figure 14 TIC of a mixture of HFBA derivatives under electron-capture negative-ion chemical ionization (ECNICI) conditions. GC/MS conditions: GC column, HP-5 (50 m × 0.2 mm i.d.); column temperature, initially at 50 °C for 0.5 min, heated to 110 °C at 50 °C min^{-1}, to 225 °C at 5 °C min^{-1}, to 280 °C at 20 °C min^{-1} and held at 280 °C for 15 min; injector and transfer line temperatures, 250 and 280 °C, respectively; carrier gas, helium at 250 kPa; ion-source temperature, 200 °C; electron energy, 150 eV. Peaks: 1 = aniline; 3 = *N*-methylaniline; 4 = 2-methylaniline; 5 = 3-methylaniline; 6 = 4-methylaniline; 8 = 2,3-dimethylaniline; 11 = 2,6-dimethylaniline; 12 = 3,4-dimethylaniline; 13 = 3,5-dimethylaniline; 15 = 2-ethylaniline; 20 = 2-methoxyaniline; 21 = 4-methoxyaniline; 22 = 2,4-dimethoxyaniline; 24 = 3,4-dimethoxyaniline; 29 = 4-chloroaniline; 33 = 3-chloro-2-methylaniline; 34 = 3-chloro-4-methylaniline; 37 = 5-chloro-2-methylaniline; 39 = 2,4-dichloroaniline; 43 = 3,5-dichloroaniline; 44 = 2,3,4-trichloroaniline; 45 = 2,4,5-trichloroaniline; 47 = 3,4,5-trichloroaniline; 52 = *N*-methyl-4-nitroaniline; 53 = 2-methyl-3-nitroaniline; 55 = 2-methyl-5-nitroaniline; 56 = 2-methyl-6-nitroaniline; 58 = 4-methyl-2-nitroaniline; 64 = 5-chloro-2-nitroaniline; 65 = 4-chloro-3-nitroaniline; 66 = 1-aminonaphthalene; 67 = 2-aminonaphthalene; 68 = 2-aminobiphenyl; 69 = 4-aminobiphenyl; 70 = 4-phenylazoaniline. Each peak corresponds to 50 pg of amine. (Reprinted from M. Longo, A. Cavallaro, *J. Chromatogr. A*, **753**, 91–100 (1996), Copyright 1996, with permission of Elsevier Science.)

Ammonia is the only base formed during the reductive catalytic decomposition of the organic compounds. This gaseous product is then dissolved in HCl–ethanol and the change in solvent conductivity is measured. Therefore, other reduction products do not cause an increase in conductivity in this solvent. The carrier gas and hydrogen reducing gas must be very pure for noise-free, sensitive operation. The solvent is conditioned in an ion-exchange resin to maintain conductivity. Although the selectivity depends on the compound and element, the selectivity ratios for the detection of nitrogen and halogen compounds versus carbon detection are 10^4–10^6 : 1 and 10^6 : 1, respectively. The sensitivity of the ELCD to chlorinated compounds is about 0.1–1 pg. Whereas the solvent used in analysis with an ELCD can be of liquid chromatographic grade, the gas flow system must be kept very clean. Carbon particles in the conductivity cell can cause spiking and noise, as can a used or dirty nickel reaction tube.

The ELCD has been applied to the analyses of several amines.[31,206] Riggin et al.[31] evaluated some selective GC detectors, such as the NPD, ELCD and photoionization detector (PID), for the analysis of aniline compounds. PID can detect components which are ionized by an ultraviolet (UV) light source. The NPD and ELCD gave similar detection limits, although the NPD gave a more stable baseline and less day-to-day variation in response. On the other hand, the PID gave a lower response, although the detection limits were improved by using a higher energy source.

3 APPLICATION IN ENVIRONMENTAL ANALYSIS

3.1 General Techniques for Sample Preparation

Amines are present in the environment at low parts per billion levels or less. When environmental samples are analyzed by GC with a nonselective detector such as an FID, many peaks with the same retention times as those of amines are often present in the chromatograms. Although GC analyses with selective detectors can

save sample preparation, a cleanup procedure for the complex sample matrix is necessary for the reliable and accurate analysis of amines. In order to remove co-eluting interferences and to preconcentrate amines, the extraction and cleanup of the sample have been performed using a number of different purification techniques, such as distillation,[22,23,38,41,46,207] liquid–liquid extraction,[25,39,45,49–55,95–103,111–118,121] adsorption with various adsorbent tubes or columns,[11,19,21,31,36,123,168–170] preparative high-performance liquid chromatography (HPLC),[156,157,162,163,165–167] solid-phase extraction (SPE) with various cartridges[13,33,34] and solid-phase microextraction (SPME).[27,35,47,48,93] Some amines can be separated by acid–base partitioning, because these compounds can be extracted with organic solvents not at low pH (<1), but at high pH (>10). Adsorption with an adsorbent tube or column is effective for the separation of amines, but it is time-consuming. Blue-cotton,[161,208] blue-rayon[158,165,166,171,208] or blue-chitin,[209] cotton, rayon or chitin bearing covalently linked copper phthalocyanine trisulfonate as a ligand can selectively adsorb heterocyclic amines and other mutagens/carcinogens having polycyclic planar molecular structures. Normal- or reversed-phase HPLC fractionations are also useful for sample preparation. SPE is simple and rapid, and good recoveries of amines are obtained. SPME, recently developed by Pawliszyn,[210] is an extraction technique using a fused-silica fiber that is coated outside with an appropriate stationary phase, and saves preparation time, solvent purchase and disposal costs, and can improve the detection limits. It has been used routinely in combination with GC and GC/MS and has been successfully applied to a wide variety of compounds, including amines.

3.2 Aliphatic Amines

GC methods for the determination of aliphatic amines using selective detectors have been applied to various environmental samples such as air,[13–18,21–23] cigarette smoke,[52] water[18,36–41] and soil.[22,23,38,41] Many of these methods have been used for free amines,[13,15,17,18,21,41,44,205] and the trace analysis of low-molecular-mass aliphatic amines in air has been performed with nitrogen-selective detectors such as NPD, CLD and GC/MS types by direct injection or the headspace technique. Derivatization methods have also been used with water and soil samples, [36–38] because these samples cannot be analyzed directly. Kuwata et al.[13] analyzed low-molecular-mass aliphatic amines in air samples in and around livestock houses by Sep-Pak C_{18} cartridge treatment and subsequent GC with thermionic detection, and detected methylamine (0–12.4 ppb) and trimethylamine (0.28–69.7 ppb) (Figure 2b and c). Gronberg et al.[17,18] developed a method for the determination of short-chain aliphatic amines in ambient air based on impinger sampling in dilute H_2SO_4, selective enrichment across a polytetrafluoroethylene (PTFE) gas membrane and quantification by gas chromatography/thermionic specific detection (GC/TSD). The enrichment step was carried out in a flow system directly connected to the GC column and methyl-, dimethyl-, trimethyl-, diethyl- and triethylamine were detected at the parts per trillion level. Kataoka et al.[52] reported the determination of secondary amines as their *N*-diethylthiophosphoryl derivatives in cigarette smoke by gas chromatography/flame photometric detector (GC/FPD). This method is selective and sensitive to secondary amines, and the detection limits of amines are 0.05–0.2 pmol. By using this method, it was confirmed that dimethylamine, pyrrolidine, piperidine and morpholine occur in main- and side-stream smokes of cigarettes, and the contents of these amines in side-stream smoke are very high compared with those in main-stream smoke. Kashihira et al.[21] analyzed trimethylamine in freezer air by GC/CLD after preconcentration with a Tenax-GC® tube, and detected 2.4 ppb of trimethylamine. Koga et al.[36] reported the determination of trace amounts of 12 aliphatic primary and secondary amines as their dinitrophenyl derivatives in waters from sewage and river by GC/MS. By using this method, low-molecular-mass aliphatic amines in water samples can be determined in the range 1–3 ppb. Avery and Junk[37] reported the determination of trace amounts of seven aliphatic primary amines in waters from tap, river and oil shale process by GC/MS based on Schiff base formation with PFBA. This method is specific for primary amines and the detection limit is 10 ppb with no sample transfers or manipulations being necessary for sample volumes of 0.5 mL. Terashi et al.[38] reported the determination of eight primary and secondary amines in river water, seawater and sea sediment by GC/MS in the SIM mode based on distillation of the sample under alkaline conditions and subsequent benzenesulfonylation. In this method, the detection limits of amines in water and sediment are 0.02–2 and 0.5–50 ppm, respectively. Pietsch et al.[39] analyzed aliphatic and alicyclic amines in wastewater samples by GC/MS after derivatization with trichloroethyl chloroformate and liquid–liquid extraction, and detected morpholine and piperidine. Sacher et al.[40] analyzed primary and secondary amines in industrial wastewater and surface water samples by GC/MS as their *N*-benzenesulfonyl derivatives, and detected methylamine, dimethylamine, morpholine and ethanolamine in concentrations up to 100 $\mu g\,L^{-1}$. Furthermore, ethylamine and diethylamine were found in concentrations up to 30 $\mu g\,L^{-1}$. Tsukioka et al.[41] reported the determination of lower aliphatic tertiary amines in pond water and bottom sediments (Figure 15a–c). These amines were determined by headspace GC/MS in the SIM mode

Figure 15 SIM chromatograms of standard aliphatic amines and environmental samples. (a) Standard aliphatic amines; (b) pond water from Suwa Lake; (c) bottom sediment from Tokyo Bay. GC/MS conditions: GC column, TC-1 (30 m × 0.53 mm i.d.); column temperature, initially 40 °C for 2 min, increased to 180 °C at 20 °C min^{-1} and held at 180 °C for 5 min; injection temperature, 180 °C; separator and ion source temperatures, 250 °C; ionization volatage, 70 eV; carrier gas, helium at 75 cm^3 s^{-1}. Peaks: 1 = trimethylamine; 2 = triethylamine-d_{15}, 3 = triethylamine; 4 = triallylamine; 5 = tripropylamine; 6 = tributylamine. (Reprinted from T. Tsukioka, H. Ozawa, T. Murakami, *J. Chromatogr.*, **642**, 395–400 (1993), Copyright 1993, with permission from Elsevier Science.)

after distillation. The detection limits for the final 40-mL samples were 5–50 ng and this method showed excellent sensitivity and selectivity.

3.3 Aromatic Amines

GC methods for the determination of aromatic amines using selective detectors have been applied to various environmental samples such as air,[19,20,24,25] cigarette smoke,[11,25,49–51,53] wastewater [31–34] and soil.[55] Becher[19] reported the determination of several aromatic amines in workplace atmosphere by gas chromatography/nitrogen–phosphorus detector (GC/NPD). Air samples are collected in three-section silica gel tubes and the amines on silica gel are eluted with 2-butanone. Garcia-Valcarcel et al.[55] determined several dinitroaniline herbicides in environmental samples by GC/NPD after solvent extraction. Schmidt et al.[33] reported a method for the selective determination of aromatic amines in water samples. This method is based on the SPE at pH 9, subsequent derivatization to the corresponding iodobenzenes and GC/ECD analysis. Aniline and nitroaniline compounds were detected in groundwater samples (Figure 16). Pieraccini et al.[25,53] reported the determination of 17 primary aromatic amines as their pentafluoropropionamides in cigarette smoke and indoor air by GC/MS in the SIM mode. Cigarettes are smoked in a laboratory-made smoking machine and the amines in the main- and side-stream smokes are trapped in dilute hydrochloric acid. It is confirmed that side-stream smoke contains total levels of aromatic amines about 50–60 times higher than those in main-stream smoke, and some aromatic amines in ambient air such as offices and houses may be derived from considerable contamination of aromatic amines in side-stream smoke. Kataoka et al.[50] analyzed aromatic amines in the cigarette smoke samples as their *N*-*n*-propoxycarbonyl derivatives (Figure 3b) and their *N*-dimethylthiophsphoryl derivatives by GC/NPD and GC/FPD (P mode), respectively, after collection of smoke samples in the same manner. Okumura et al.[45] determined aniline and related aromatic amines in river water and sediment samples by GC/MS in the SIM mode after liquid–liquid extraction and steam distillation. The detection limits of the anilines in water and sediment samples were 4.2–31 pg mL^{-1} and 1.2–4.0 ng mL^{-1}, respectively. Longo and Cavallaro[46] analyzed aromatic amines in groundwater samples as their heptafluorobutyryl derivatives by gas chromatography/electron-capture negative-ion chemical ionization mass spectrometry (GC/ECNICIMS) after concentration with a Kuderna–Danish evaporator. Muller et al.[47,48] reported the determination of aromatic amines by SPME and GC/MS. This method was simple, rapid, precise and sensitive and various groundwater samples could be directly analyzed (Figure 17a and b). Guan et al.[35] also analyzed nitroaniline herbicides in river water by SPME and GC/ECD.

Figure 16 GC/ECD of a groundwater from Stadtallendorf. GC conditions and peak numbers as in Figure 9. (Reprinted from T.C. Schmidt, M. Less, R. Haas, E. von Low, K. Steinbach, G. Stork, *J. Chromatogr. A*, **810**, 161–172 (1998), Copyright 1998, with permission from Elsevier Science.)

3.4 *N*-Nitrosamines

GC determinations of *N*-nitrosamines in environmental samples have been carried out in indoor and outdoor air,[94,95] combustion smoke,[52,82,96–103] water,[104–107,110] rubber products,[111–118] metalworking fluids,[120] drug formulations[121,122] and agricultural chemical formulations.[110,123,124] In most of them, *N*-nitrosamines are directly analyzed as the free form by GC/TEA, based on the detection of the chemiluminescence emitted from a reaction between releasing NO radicals and ozone after thermal cleavage of N–NO bond in *N*-nitroso compounds. Fadlallah et al.[95] determined volatile nitrosamines in the factory environment by GC/TEA (Figure 11b). Air samples were collected by drawing air through a Thermosorb/N cartridge, and then the sorbent was eluted with methanol–dichloromethane (1 : 3). Brunnemann et al.[97–100] analyzed volatile and tobacco-specific *N*-nitrosamines in main- and side-stream smoke of cigarette and tobacco by GC/TEA. The smoke sample was collected in citrate buffer (pH 4.5) containing 20 mM ascorbic acid and then extracted with dichloromethane. *N*-Nitrosodimethylamine, *N*-nitrosopyrrolidine, *N*-nitrosomethylethylamine and some tobacco-specific nitrosamines such as *N*-nitrosonornicotine, 4-(methyl-

Figure 17 TICs of spiked water and groundwater samples extracted by SPME. (a) Water solution spiked with 10 ng mL^{-1} aromatic amines; (b) groundwater collected near an industrial area north of Milan, Italy. GC/MS conditions: GC column, base-deactivated PTA-5 (30 m × 0.25 mm i.d.); column temperature, initially at 60 °C for 5 min, increased to 250 °C at 10 °C min^{-1} and held at 250 °C for 3 min; injector and detector temperatures, 260 and 280 °C, respectively; carrier gas, helium at 40 kPa; detection, SIM mode. Peaks: 1 = *o*-toluidine; 2 = *p*-chloroaniline; 3 = 2,4- and 2,5-dichloroaniline; 4 = 3,5-dichloroaniline; 5 = 3,4-dichloroaniline. (Reprinted from L. Muller, E. Fattore, E. Benfenati, *J. Chromatogr. A*, **791**, 221–230 (1997), Copyright 1997, with permission from Elsevier Science.)

nitrosamino)-4-(3-pyridyl)butanal and 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone were detected. The *N*-nitrosamines in environmental tobacco smoke, to which both smokers and nonsmokers are exposed, have received a great deal of attention as a source of indoor pollution. Tomkins et al.[106,107] determined *N*-nitrosodimethylamine in drinking water and groundwater at the parts per trillion level by GC/CLD (nitrogen mode) (Figure 18a–c). Furthermore, they developed new sample preparation procedure for the extraction of *N*-nitrosamines using a C_{18} membrane extraction disk. Thompson et al.[114,115] reported the determination of *N*-nitrosamines in rubber nipples and pacifiers at the parts per billion level by GC/TEA (Figure 19a–c). In these samples, *N*-nitrosodibutylamine was the principal *N*-nitrosamine found, along with trace amounts of *N*-nitrosodimethylamine, *N*-nitrosodiethylamine and *N*-nitrosopiperidine. The occurrence of *N*-nitrosamines in baby bottle rubber nipples and pacifiers is of special concern because traces of these amines may migrate to infant saliva during sucking, and then be ingested. Although GC/TEA can be used as a sensitive and specific method for the analysis of *N*-nitroso compounds, it is too expensive to use in many laboratories. As an alternative method, Kataoka et al.[52,96] reported the determination of seven *N*-nitrosamines by GC/FPD (P mode). The method is based on denitrosation with hydrobromic acid to produce the corresponding secondary amines and subsequent diethylthiophosphorylation of secondary amines. By using this method, it was confirmed that *N*-nitrosodimethylamine, *N*-nitrosopyrrolidine and *N*-nitrosopiperidine occur in main- and side-stream smoke of cigarettes. In addition, some *N*-nitrosamines in various environmental samples were determined by GC/NPD,[123] GC/ECD[120] and GC/MS.[103,105,124]

3.5 Heterocyclic Amines

Most heterocyclic amines are polar and of low volatility, and tend to elute as broad and tailing peaks owing to strong adsorption on the column and injector during

Figure 18 Detection of *N*-nitrosodimethylamine in two sources of drinking water, (a) and (b). The corresponding synthetic groundwater blank (c) exhibits a smaller concentration of *N*-nitrosodimethylamine than in either source. GC conditions: column, Rtx-200 (cross-bond trifluoropropylmethyl, 30 m × 0.53 mm i.d.); column temperature, initially isothermal at 35 °C for 5 min, programmed from 35 to 175 °C at 6 °C min^{-1} and held at 175 °C for 5 min; injector temperature, 150 °C, carrier gas, helium at 4 mL min^{-1}; detector, CLD (nitrosamine-selective mode); detector furnace, 250 °C. NDMA = *N*-nitrosodimethylamine. (Reprinted by permission from B.A. Tomkins, W.H. Griest, C.E. Higgins, *Anal. Chem.*, **67**, 4387–4395 (1995), Copyright 1995, American Chemical Society.)

GC analysis, when they are analyzed without derivatization. Therefore, the analysis of these amines has been generally carried out by HPLC.[211] For the GC analysis of heterocyclic amines, several derivatizations using acetic anhydride, trifluoroacetic anhydride, HFBA, pentafluorobenzyl bromide, 3,5-bistrifluoromethylbenzyl bromide and 3,5-bistrifluoromethylbenzoyl chloride have been tested.[141–144,146,168,173,176] However, acylation with acid anhydrides yielded derivatives with very poor GC properties. The alkylation products with pentafluorobenzyl bromide, 3,5-bistrifluoromethylbenzyl bromide and 3,5-bistrifluoromethylbenzoyl chloride had good GC properties for some heterocyclic amines. However, these methods gave a mixture of mono- and dialkylated forms and were used for GC/MS analysis but not for GC analysis. Recently, Kataoka and Kijima[198] developed a simple and rapid derivatization method for the GC analysis of mutagenic heterocyclic amines. Ten heterocyclic amines were converted into their *N*-dimethylaminomethylene derivatives with *N*,*N*-dimethylformamide dimethyl acetal and measured by GC/NPD. As shown in Figure 20(a), these heterocyclic amines were separated within 7 min, although AαC and 2-aminodipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-2) co-eluted. The detection limits of these compounds ranged from 2 to 15 pg. By using this method, AαC, 3-amino-1,4-dimethyl-5*H*-pyrido[3,4-*b*]indole (Trp-P-1), 3-amino-1-methyl-5*H*-pyrido[3,4-*B*]indole (Trp-P-2), 2-amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole (Glu-P-1), IQ, 2-amino-3,4-dimethylimidazo[4,5-*f*]quinoline (MeIQ), and 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]-pyridine (PhIP) were determined in several combustion smoke samples[158] (Figure 20b and c). On the other hand, few GC/MS (SIM mode) data using positive-ion electron ionization and negative-ion CI on the analysis of heterocyclic amines after derivatization are available. Vainiotalo et al.[168] analyzed MeIQx and DiMeIQx in cooking fumes as their 3,5-bistrifluoromethylbenzyl derivatives by GC/MS in the SIM mode (Figure 21a and b). The cooking fumes were collected through a glass-fiber funnel into a sampler which consisted of two glass-fiber filters and an XAD-2 sorbent tube. Although these heterocyclic amines give a mixture of mono- and dibistrifluoromethylbenzyl derivatives, the spectra of the dibistrifluoromethylbenzyl derivatives possess high-mass fragment ions suitable for SIM work. When ions at *m*/*z* 438 MeIQx and *m*/*z* 452 DiMeIQx were specially monitored, the detection limit of these compounds was 2 pg.

4 CONCLUSIONS

Environmental pollution is recognized as an important problem for public health, because it is very close to the daily life of people throughout the world. The occurrence and toxicity of hazadous chemicals in the biosphere have received a great deal of attention in recent years. Neglect of environmental pollution caused widespread contamination of air, soil and water, unhealthy conditions for workers and the loss of many precious natural resources. Therefore, environmental measurements are essential as a significant index of risk assessment not only in establishing the quantitative relationship between exposure and response to these pollutants, but also in establishing the natural baseline conditions in the

Figure 19 GC/TEA of standard *N*-nitrosamines and pacifier sample. (a) Standard mixture containing 50 ng mL^{-1} each of *N*-nitrosamine; (b) reagent blank; (c) pacifier sample. GC conditions: column, 10% Carbowax™–2% KOH on Chromosorb® W AW (6 ft × 4 mm i.d.); column temperature, programmed from 150 to 190 °C at 4 °C min^{-1}; injector temperature, 250 °C, carrier gas, nitrogen at 40 mL min^{-1}; detector, TEA; detector furnace, 500 °C; cold trap, −150 °C. Peaks: NDMA = *N*-nitrosodimethylamine; NDEA = *N*-nitrosodiethylamine; NDPA = *N*-nitrosodipropylamine; NDBA = *N*-nitrosodibutylamine; NPIP = *N*-nitrosopiperidine; NPYR = *N*-nitrosopyrrolidine; NMOR = *N*-nitrosomorpholine. environment. Toxic amines, described in this article, are widely distributed in a number of ambient environmental components such as air, diesel exhaust, cigarette smoke, cooking fumes, river water, sewage water, soil and chemical products. The presence of these amines in the environment may be more extensive than previously thought and humans are continually exposed to these compounds in normal daily life. Therefore, monitoring of amines in the environment is very important to preserve human health and the natural environment, and practical and reliable methods for determining accurate exposure levels of these amines need to be established. For this purpose, various analytical methods have been developed. In particular, GC is one of the most useful techniques for the simultaneous determination of most amines. However, the amines in environmental samples are generally present at very low concentrations and are often to be found among complex matrices containing a number of co-existing substances. Therefore, GC detectors for environmental analysis must be not only sensitive to minute amounts of analytes, but also selective enough to discriminate against reasonable amounts of co-existing substances.

The nitrogen-selective thermionic detectors, the nitrosamine-specific detector TEA and GC/MS have been widely used for obtaining high sensitivity and selectivity. In addition, conversions of amines into fluorinated derivatives to introduce an ECD response and into sulfur- and phosphorus containing derivatives to introduce an FPD response have been devised for these purposes.

GC with nitrogen-selective thermionic detection is highly sensitive and selective for amine analysis, and available in most laboratories. Although the selectivity and sensitivity of thermionic detectors depend on the flow rates of hydrogen, air, make-up gas and carrier gas, a relatively stable response is realized using a flameless type of thermionic detector. GC/MS, capable of measuring simultaneously retention time and molecular mass, is a powerful technique for the identification and quantification of amines in complex matrix samples. The TEA is also selective and sensitive for *N*-nitroso compounds, but its response depends on the pyrolysis temperature. Although

Figure 20 Gas chromatograms obtained from (a) standard heterocyclic amines, (b) cigarette side-stream smoke and (c) combustion smoke of semidried fish. GC conditions: column, connected DB-1 (10 m × 0.25 mm i.d.) and DB-17ht (10 m × 0.25 mm i.d.); column temperature, programmed from 230 to 280 °C at 10 °C min^{-1}, from 280 to 330 °C at 25 °C min^{-1} and held at 330 °C for 1 min; injection and detector temperatures, 340 °C; carrier gas, helium, programmed from 180 to 230 kPa at 10 kPa min^{-1}, from 230 to 280 kPa at 25 kPa min^{-1} and held at 280 kPa for 1 min; split ratio, 10 : 1; detector, NPD. Peaks: 1 = AαC (2-amino-9*H*-pyrido[2,3-*b*]indole); 2 = Glu-P-1; 3 = Trp-P-1; 4 = Trp-P-2; 5 = IQ; 6 = MeIQ; 7 = MeIQx (2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline); 8 = DiMeIQx (2-amino-3,4,8-trimethylimidazo[4,5-*f*]quinoxaline); 9 = PhIP; 10 = TriMeIQx (2-amino-3,4,7,8-tetramethylimidazo[4,5-*f*]quinoxaline) (internal standard). GC/MS in the SIM mode and GC/TEA are most effective for the analysis of a specified amine, they require sophisticated and expensive equipment that is beyond the reach of many laboratories. GC/FPD and GC/ECD require the derivatization of amines to the corresponding halogen- and sulfur- or phosphorus-containing compounds, respectively, but thereby offer increased selectivity and sensitivity for specific amines. GC methods with selective detectors, described in this article, have advantages and disadvantages and so far there are no all-powerful analytical methods.

The choice of an analytical method depends on the presence of amines in the environment at low parts per billion levels or less and the variety and complexity of the sample. In order to achieve an efficient isolation and preconcentration of amines, several methods of sample preparation for the analysis of various environmental samples have been developed using a number of different purification techniques, such as distillation, liquid–liquid extraction, column chromatography, SPE, extraction with mutagen specific adsorbent and preparative HPLC. The combination of these techniques is used successfully for

Figure 21 GC/MS (SIM mode) traces of (a) fumes from fried beef/pork and (b) a standard sample containing 5 ng of MeIQx, 1.5 ng of 4,8-DiMeIQx and 2.5 ng of 7,8-DiMeIQx. The base peaks of the di-bis-TFMB (trifluoromethylbenzyl) derivatives were monitored (MeIQx, *m*/*z* 438; DiMeIQx, *m*/*z* 452). GC/MS conditions: column, HP-5 (20 m × 0.2 mm i.d.); column temperature, initially isothermal at 70 °C for 1 min, increased to 280 °C at 25 °C min^{-1} and held at 280 °C for 5 min; injector temperature, 250 °C; carrier gas, helium at 1 mL min^{-1}; ionization voltage, 70 eV; emission current, 300 μA. (Reproduced by permission of Springer-Verlag from S. Vainiotalo, K. Matveinen, A. Reunanen, *Fresenius' J. Anal. Chem.*, **345**, 462–466 (1993), Copyright Springer-Verlag.)

the extraction and purification of amines. However, many of these methods are time-consuming, laborious and give low recoveries for some specific amines. On the other hand, the SPME method is simple and rapid, and is directly applicable to the sample.

Environmental analysis has benefited from the recent advances in GC, including high-resolution columns for complex mixtures and improved sensitivity and selectivity in detection. Powerful selective detection tools coupled with the many technological advances in capillary columns, software and hardware over the past decade have added a new dimension. Measurement techniques in environmental analysis will become increasingly more sensitive and selective in the future. For this purpose, further developments in selective GC detectors and in capillary columns, e.g. shorter inactive columns with smaller internal diameters giving ultrahigh column efficiency and speed, higher temperature phases and exterior coating for the fused-silica tubing, will permit the analysis of both high-temperature and highly volatile amines. Furthermore, simple, rapid and automated separation and analysis of compounds in various environmental samples will be achieved by combination with convenient sample preparation techniques such as SPME.

ABBREVIATIONS AND ACRONYMS

AαC	2-Amino-9*H*-pyrido[2,3-*b*]indole
AFID	Alkali Flame Ionization Detector
CI	Chemical Ionization
CLD	Chemiluminescent Detector
DiMeIQx	2-Amino-3,4,8-trimethylimidazo[4,5-*f*]quinoxaline
ECD	Electron-capture Detector
ECNICI	Electron-capture Negative-ion Chemical Ionization
EI	Electron Impact Ionization
EIMS	Electron Impact Ionization Mass Spectrometry
ELCD	Electrolytic Conductivity Detector
FID	Flame Ionization Detector
FPD	Flame Photometric Detector
FTD	Flame Thermionic Detector
GC	Gas Chromatography
GC/CLD	Gas Chromatography/Chemiluminescent Detection
GC/ECD	Gas Chromatography/Electron-capture Detector
GC/ECNICIMS	Gas Chromatography/Electron-capture Negative-ion Chemical Ionization Mass Spectrometry
GC/FPD	Gas Chromatography/Flame Photometric Detector
GC/MS	Gas Chromatography/Mass Spectrometry

GC/NPD	Gas Chromatography/Nitrogen–Phosphorus Detector
GC/TEA	Gas Chromatography/Thermal Energy Analysis
GC/TSD	Gas Chromatography/Thermionic Specific Detection
Glu-P-1	2-Amino-6-methyldipyrido[1,2-*a*:3′,2′-*d*]imidazole
Glu-P-2	2-Aminodipyrido[1,2-*a*:3′,2′-*d*]-imidazole
HFBA	Heptafluorobutyric Anhydride
HPLC	High-performance Liquid Chromatography
IARC	International Agency for Research on Cancer
IQ	2-Amino-3-methylimidazo[4,5-*f*]quinoline
ITD	Ion Trap Mass Detector
MeIQ	2-Amino-3,4-dimethylimidazo[4,5-*f*]quinoline
MeIQx	2-Amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline
MSD	Mass-selective Detector
NICIMS	Negative-ion Chemical Ionization Mass Spectrometry
NPD	Nitrogen–Phosphorus Detector
OPA	*o*-Phthaldialdehyde
PFBA	Pentafluorobenzaldehyde
PFPA	Pentafluoropropionic acid
PhIP	2-Amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine
PID	Photoionization Detector
PTFE	Polytetrafluoroethylene
SIM	Selected-ion Monitoring
SPE	Solid-phase Extraction
SPME	Solid-phase Microextraction
TEA	Thermal Energy Analyzer
TFMB	Trifluoromethylbenzyl
TIC	Total Ion Chromatogram
TriMeIQx	2-Amino-3,4,7,8-tetramethylimidazo[4,5-*f*]quinoxaline
Trp-P-1	3-Amino-1,4-dimethyl-5*H*-pyrido[3,4-*b*]indole
Trp-P-2	3-Amino-1-methyl-5*H*-pyrido[3,4-*b*]indole
TSD	Thermionic Specific Detector
UV	Ultraviolet
